A.—Several different conditions are covered by the above question. Senile keratosis, especially met with in those who have lived in the Tropics, and often pre-malignant, usually requires radiotherapy; otherwise the CO_2 pencil applied for 30 seconds may be adequate. The simpler pigment patches clear up after light freezing with CO_2, and this also applies to the true seborrhoeic warts, which are, however, more common on the trunk than on the face. Painting with pure carbolic is also recommended for this condition.

Removing Blackheads

Q.—*What is the best method of getting rid of "blackheads" on the face? Is there any way to prevent their developing?*

A.—First steam the face, or apply a hot sponge for 5 to 10 minutes; then with a special instrument *gently* remove the blackheads, leaving those alone which offer any degree of resistance. A simple extractor can be made from a piece of laboratory glass tubing, 1 in. in length, the sharp edge rounded off in the Bunsen flame. This, with salicylic acid 3 or 4% in soft paraffin, provided it is tolerated, assists by its peeling action.

Tubercle-infected Fomites

Q.—*In many sanatoria patients do leather-work, make jewellery, toys, table-mats, knitted articles, etc. Is there any definite instance of infection following the selling of such articles to people outside? Theoretically all such things are infected, whether the maker is sputum-positive or not. Should not the clothes and belongings of a patient before discharge be put through some form of terminal disinfection? Is it wise for a patient to take home any books he may have acquired during his stay in a sanatorium?*

A.—The part which inanimate objects (fomites) play in the spread of tuberculous infection is probably small but is obviously difficult to assess. The greatest risk would be to young children, who instinctively put everything they handle into the mouth; and in a household where there is a tuberculous case (often undiagnosed) spread of infection to infants by fomites almost certainly occurs, for a fair proportion of abdominal and glandular tuberculosis is due to the human type of tubercle bacillus. Tubercle bacilli exposed to daylight, directly or even through glass, have a limited viability—a few hours to a few days—so that surface contamination of leather goods and hardware with infected droplets is unlikely to be a serious hazard to those who buy these goods. Besides, the mordants used in dyeing leather are probably bactericidal, and prudent people would wash any hardware articles brought from a sanatorium. Knitted and other woollen garments are usually sterilized before release. As for clothing, the patient who is up and wearing outdoor clothes has been trained to the use of his sputum flask, and is unlikely to contaminate his suit by expectoration. Coughing in a sanatorium is a remarkably rare phenomenon, and patients cover their coughs with the handkerchief issued daily and kept in a "special pocket."

Books are perhaps the greatest danger, especially if an infective patient "wet-thumbs" the pages. However, experiments have shown that tubercle bacilli can rarely be recovered after a month from books heavily contaminated with tuberculous sputum and kept in a cupboard (see *Publ. Hlth.*, 1940, **53**, 157). Thus the patient wishing to take home books acquired while in the sanatorium may safely do so if he puts them in quarantine for 3 to 4 weeks. Dry heat is the only form of active sterilization applicable to books, but even this cannot be considered harmless. Outside "airing" would reduce the period of infectivity.

Body Temperature Readings

Q.—*There seems to be a difference of opinion about when and how to take the correct temperature of the body, and I should be glad of an expert opinion. A Kew certificate clinical thermomete starting at 96.5° in my case (I am liable to T. 99° in the evenings from tracheitis) will hardly move in 2 minutes and will take 1 minutes to reach 99° (at the same time I have symptoms compatible with a rise of temperature). A colleague says that a 30-second thermometer should rise within a minute, and if kept in place will continue to do so, also that the temperature rises above normal in the ordinary way. Are the last two true? Is the temperature taken per rectum or by placing a thermometer in the stream of urine to be considered as correct, and how does such compare with the temperature taken in the mouth?*

A.—Although thermometers are described as 1/2-minute or 1½-minute, these are purely technical specifications and have little bearing on their use in practice. No clinical thermometer can be expected to come into equilibrium with the body in less than 2 minutes however it is used. Nurses are taught not to shake the mercury below 95°, to minimize delay. For accurate records the rectal temperature is preferred and the thermometer is left *in situ* for 5 minutes. In the mouth it is generally agreed that it may take up to 10 minutes for equilibrium to be obtained; nevertheless fo ordinary work it is usually sufficient to read the temperature at, say, 3 minutes and then at short intervals thereafter until the difference between successive readings approaches zero. Readings in the axilla and groin are the least satisfactory, particularly in thin people. The normal range of temperature was discussed in an answer on May 29, 1943 (p. 683). For the rectum it is 97.7° to 99.5°. Mouth temperatures are 1.0° lower than rectal temperatures, and axillary temperatures are 0.5° lower than mouth temperatures. The time of the maximum temperature is usually between 5 and 8 p.m., but in cases of suspected pyrexia it may be desirable to take the temperature 4-hourly or even 2-hourly so as not to miss the peak. The temperature may exceed the normal range after exertion though it should return to normal in 1/2 to 1 hour. Mouth temperatures are higher when there are local inflammatory lesion in the mouth, and lower when the nose is blocked and the mouth cannot be kept closed. The temperature in a stream of urine i 0.5° below the rectal. Urinary temperatures are of most value i cases of exposure, when the temperature may be too low to recor with a clinical thermometer and the temperature of the urine ma be recorded with a bath thermometer.

Infection of Urinary Tract

Q.—*A woman aged 55 had a deformed kidney removed man years ago. Blood urea is normal, and urine usually has man B. coli. Every few weeks she has a shivering attack and frequency in spite of taking prophylactic courses of mandelic acid and citrat alternately. Is a vaccine of use? The remaining kidney wa investigated at the time of the operation.*

A.—The efficacy of mandelic acid treatment is only detracted fron by alternating periods on potassium citrate: they simply serve t give the bacteria a congenial rest from acid assault. Has a adequate course of mandelic acid been given? That is to say, on lasting 10 days and reinforced by the administration of ammoniu chloride in such doses as demonstrably to reduce the *p*H of th urine to 5.0. If this fails, a course of sulphanilamide should b tried. The persistence of the infection and the history of th removal of a deformed kidney suggest that the condition may be pyelonephritis rather than a simple infection of the urinary trac (it would be of interest to know the blood pressure); if this is s sulphanilamide has a better chance than mandelic acid, since th latter acts only in the urinary tract itself. Opinion on the utilit of an autogenous vaccine in such conditions is divided; its likeli hood of success would presumably depend, at least in part, on whethe deficient resistance to infection is the sole cause, or whether ther is also some structural abnormality of the urinary tract predisposin to chronic infection.

Early Signs of Syphilis

Q.—*Are there any early pathognomonic signs or symptoms of developing primary syphilitic lesion of the penis during the perio of 1 to 2 weeks after intercourse? A patient who had intercours 17 days ago complains of soreness and increased redness of th prepuce and glans, and wishes to be assured. Is it too early to rel on a Wassermann test?*

A.—The only pathognomonic sign of early syphilis is a lesio usually a sore, in which *Spirochaeta pallida* can be demonstrate The shortest incubation period of syphilis is said to be 10 days, th average being about 25 days. The soreness and increased redne of the prepuce and glans may be due to balanitis, but if there any breach of surface it would be wise to examine scrapings f *Spirochaeta pallida* with the dark-ground microscope. This shoul be repeated at intervals. If possible the contact should b xamined for signs of syphilis. A Wassermann test is not likely to e positive till a sore has been present for some days—i.e., 4 to 5 weeks from the date of infection.

Cause and Treatment of "Stitch"

Q.—*An undergraduate of 18 who is a keen representative of his university in cross-country running develops while running a stitch" in his side. What are the latest theories as to causation, athology, and treatment of "stitch"?*

A.—The "latest theory" as to the causation of "stitch" on exertion may be found in an article by Capps (*Arch. intern. Med.*; 1941, **68**, 94). He attributes it to ischaemia of the diaphragm—an idea which is attractive through analogy with other ischaemic occurrences f pain or cramp, such as angina pectoris and intermittent claudication, and is with difficulty proved or discredited, especially as, up to the present, the genesis of this very familiar bugbear of athletes as not been satisfactorily settled. In the *Guy's Hospital Gazette* 1932, **46**, 165) some investigations are described which would appear to exonerate or exclude the diaphragm. Volunteers undertook iolent exercise shortly after a meal, with the consequent development of stitch, yet fluoroscopic examination while the pain was resent showed that diaphragmatic movements were full and nrestricted.

A plausible explanation advanced was that of a sort of physiological visceroptosis. In the erect attitude the heaviest viscera are partly supported by the musculature of the anterior abdominal wall. When the walls are unable to provide adequate support the vertical strain on the peritoneal ligaments is intensified. During running there are intervals of complete relaxation of the muscles that maintain intra-abdominal pressure; and if violent jolts coincide repeatedly with relaxation (during respiration) the result is an intermittent ugging on the ligaments. It is evident why an additional load in the stomach, through a meal having been taken a comparatively short time before exercising, will be a contributory factor; and also why the symptom is more likely in cross-country running—as opposed to a cinder track—since rough uneven surfaces are inevitably ncountered with jolting of the body, especially if the runner is of relatively asthenic build with a light springy action. It has been observed that riding on a camel with jerky action, or on a motor ycle over a rough road, often produces the same sort of pain. This explanation may apply to some cases, but it is equally likely that the pleura may be the sensitive structure implicated through tension from the diaphragm. Localization of the pain will be most ommonly over the costal cartilages which are least supported and have the maximum excursion—viz., the 10th and 11th, to which are ttached the longest fibres of the diaphragm. It may well be that a relatively poor blood supply to the diaphragm or intercostal muscles also enters into the aetiology. Furthermore, I am convinced that xposure to cold is of consequence—another feature which comes into line with Capps's opinion.

Since "treatment" is practically limited to cessation of the xercise, it may be presumed that the inquirer is really interested n possible prevention. I have been disappointed to find how little an be done. It appears as if the subject has a constitutional predisposition, whether for anatomical, physiological, or mechanical reasons. The obvious precaution of avoiding a heavy meal within two hours of the effort hardly needs mention, but I would again refer to the influence of cold as a factor. It is wise to warm up as much as possible before facing the outer air, and as the wrists ppear for some reason to be peculiarly vulnerable, I advise wearing long mittens. I have had reason to believe that this simple procedure has been helpful in some cases.

Life of Sperms

Q.—*It is stated in Eden's "Manual of Midwifery" that a living perm has been found in the Fallopian tubes 3½ weeks after the last intercourse. If this is so, does it not completely negative "safe" periods and contradict the general opinion of the life of the sperm in the female genital organs?*

A.—There are isolated reports of motile spermatozoa being found in the Fallopian tubes 2 and 3 weeks after coitus, the most requently quoted being the two cases of Nürnberger (*Mschr. Geburtsh. Gynäk.*, 1920, **53**, 87), where active spermatozoa were found in tubes excised 13 and 14 days after the last admitted act of oitus. Such reports, however, should be accepted with reserve because they depend for the most part on the patient's uncoroborated statement as to the date of the last coitus; and again most workers who have searched for motile spermatozoa, under similar conditions, have failed to find them. Nevertheless, there are also accounts, and perhaps better substantiated ones, of the finding of motile spermatozoa in the cervix and uterus 5 to 8 days after coitus, o it seems possible that under special conditions spermatozoa can, on rare occasions, survive in the female genital tract for a longer period than that usually stated. To explain such findings, it is postulated that a thick cervical plug of mucus may, by depriving embedded spermatozoa of oxygen and leaving them bathed in carbon dioxide of their own production, maintain them in a state of suspended animation, so that when liberated and placed in a more favourable medium they may become motile several days later.

The general opinion that the spermatozoa of animals with extra-abdominal testes (including man) do not survive, or at least do not retain their reproductive vigour, for longer than 48 hours after their entrance into the female genital tract is certainly not refuted by the findings mentioned above. Indeed, this opinion has been formulated in spite of them—or at any rate only after taking them into consideration. It is based on a large body of scientific evidence derived from all manner of studies on the viability of spermatozoa of lower animals, the higher apes, and man, in the male and female genital tracts, in various tissue fluids, and in media of all kinds under varying conditions. On such matters there is now an extensive literature. So those textbooks which, in presenting the problem fairly, quote the reports mentioned, mostly conclude that it is doubtful whether human spermatozoa retain their ability to fertilize the ovum for longer than 2 to 3 days after coitus—e.g., Eden and Holland, *Manual of Obstetrics*, 1937 edition. It would seem more reasonable to suggest that the general opinion as to sperm viability, well founded as it is, raises doubts as to the accuracy of the few observations to the contrary, or at least justifies their being regarded as "freaks"

The existence of a safe period is not affected by these observations, particularly as it is recognized that such periods are relatively, rather than absolutely, safe, and that they are generally, rather than universally, applicable. Fruitful coitus during the "safe period" is not very rare, but even then, according to present evidence, it is more likely to be the result of a variation in the time of ovulation than of the prolonged survival of the spermatozoa.

Oligospermia

Q.—*Is any treatment possible for a man, examined because of his wife's alleged sterility, who shows a low sperm count, decreased viability, and abnormal forms? What is the significance of semen which does not liquefy and become homogeneous? Are any of these defects more important than others?*

A.—In general the hormone treatment of oligospermia is unsatisfactory and does not yield encouraging results. Theoretically, and in animals, pituitary gonadotrophic extract or that obtained from pregnant mares' serum does stimulate the seminiferous tubules to activity—e.g., in a hypophysectomized animal. In man the results are poor, especially when the total sperm count is under 10 millions per c.cm. (normal count, 100 millions per c.cm.), but occasionally good results are recorded, which critical observers believe to be *post* rather than *propter*. Some have found that small doses of testosterone propionate, 5 mg. injected twice weekly, stimulate spermatogenesis, though it is well known that large doses inhibit spermatogenesis. Where biopsy of the testes shows a histological picture incapable of being influenced physiologically, hormone therapy will have no effect. The significance given both to the degrees of viability and to abnormal forms varies with different observers and different methods. Some consider that up to 20% of abnormal forms does not indicate lowered fertility. Semen which does not liquefy is generally thought to be characteristic of low fertility, but again the criteria are not absolute. In my opinion seminal fluid which contains more than 20 million spermatozoa per c.cm., and which shows active movement of the spermatozoa in a fresh specimen, is unlikely to be the cause of sterility, and these two criteria are perhaps the most important of those mentioned

Cardiac Failure after Convulsion Therapy

Q.—*In the acute cardiac or respiratory failure which occasionally follows chemical or electrical convulsive therapy in mental disorders, is nikethamide contraindicated? Is atropine the drug of choice, or should no drugs be administered?*

A.—There has been comparatively little experience of these states, and very few reports. Accordingly we do not know enough to say much. The evidence is that they are usually vagal in origin, from which it would follow that the drug of choice is atropine The condition usually passes off quite rapidly with artificial respiration. It is much more likely to occur when an insufficient dosage or voltage has caused, not an epileptic fit, but a "sub-shock." With the electrical method, attempts to obtain a fit should be abandoned for the day if as many as three sub-shocks have resulted. Some patients need much higher voltages than others.

Ptyalism and Lacrimation

Q.—*What is the cause of ptyalism and lacrimation in an elderly man, and what is the treatment for these conditions?*

A.—Unilateral ptyalism and lacrimation would suggest a lesion in the seventh cranial nerve root, the geniculate ganglion, or the great superficial petrosal nerve on the same side. An irritative lesion in the area served by the sensory route of the fifth nerve should also be considered; ptyalorrhoea has also been attributed to a functional disorder of the trigeminal nerve akin to tic douloureux, and it is possible that lacrimation might occur under the same circumstances. The phenomenon of "crocodile tears," in which the normal flow of saliva at meal times is accompanied by lacrimation, is due to injury to the chorda tympani branch of the seventh cranial nerve. Bilateral salivation and lacrimation in an elderly man would suggest either paralysis agitans or vascular degenerative changes in the cortical vessels. Presuming one of these two conditions was responsible, treatment should be by atropine or stramonium, pushed, if necessary, to the limit of tolerance as shown by disturbance of ocular accommodation.

Novocain Injections

Q.—*It is very easy to pierce a vein with the fine needle used by dentists. The anaesthetic solution usually contains 3% novocain and a variable amount of adrenaline (about 0.00002 gr. per c.cm. or more). What are the dangers of direct injection into the blood stream? How much is due to novocain and how much to the adrenaline content?*

A.—The dangers of direct injection of the anaesthetic solution into the vascular system are not great. It is unlikely that enough will enter the blood stream to produce noteworthy toxic effects unless the patient has a marked idiosyncrasy to one or other of the drugs. Intravenous administration of adrenaline is a dangerous procedure, and it is possible that the tachycardia and other systemic effects may be due to small amounts of adrenaline getting into the blood stream. It is more likely, however, that these unpleasant effects are the results of emotional disturbance causing an increase in the secretion of the adrenal medulla.

Labyrinthine Vertigo

Q.—*Is labyrinthine vertigo always associated with deafness, or can it be associated in mild early cases with hyperacusis? I find the latter vaguely referred to by Wheeler and Jack. In a case of recurrent vertigo with nausea and vomiting and slight nystagmus, does the presence of hyperacusis rather than deafness rule out labyrinthine disturbance?*

A.—Hyperacusis, or more properly dysacusis, occurs after head injuries, and also in functional conditions. Labyrinthine vertigo is always associated with some deafness of the affected ear, and it is possible that the case described is of a functional nature.

A Difficult Arthritic Case

Q.—*A man aged 59, with generalized rheumatoid arthritis, came to me last year with his right leg bent and the knee inflamed. I applied weight extension and have now put it at rest straight for 9 months. This knee now appears normal, but he has not been able to use his caliper because the other knee is inflamed. Is it safe for him to use—i.e., stand on—the right leg now, or will the disease become active again if he attempts to stand on it?*

A.—It is difficult to give an opinion on this case without further details, such as the sedimentation rate as an indication of the existence of an active infective process, and radiographs of the affected joints to show the actual condition of the articular surfaces and the density of the bones themselves. Assuming, however, that the sedimentation rate is normal or nearly so, it is likely that standing for short periods would not have any ill effects, or even walking for short distances in the house. The occurrence of inflammation, while suggestive of active disease, may be due only to the trauma of excessive use on damaged synovial tissues.

Arterial Disease

Q.—*Is the age of 38 too young to find a condition of arteriosclerosis, and can an arteriosclerosis occur in the mesenteric vessels without there necessarily being evidence of its presence in the peripheral superficial vessels?*

A.—Severe arterial disease, such as atheroma, may sometimes be found at a much earlier age, particularly in the coronary arteries. Atheroma would be the most likely form of arterial disease in the mesenteric artery. The peripheral superficial arteries give no indication of the presence of atheroma in the internal arteries. Polyarteritis nodosa may occur in such vessels as the mesenteric artery; and superficial arteries—e.g., the temporal—may suggest its presence.

INCOME TAX

Deduction of Tax from Salary

E. G. is in receipt of a pension, and also of remuneration from an appointment under a local authority. He is unable to reconcile the amounts of tax deducted with his circumstances.

⁂ The difficulty probably arises from the fact that while the total amount of tax to be paid depends on the total income and total allowances, as a matter of law each separate source of income requires to be dealt with separately. In the circumstances we suggest that a personal discussion at the office of the inspector of taxes, preferably by appointment, is most likely to clear up the matter.

LETTERS, NOTES, ETC.

Answers Supplemented

Dr. W. **ST. AUBYN HUBBARD** (Falmouth) writes: In the *B.M.J.* o Sept. 16 (p. 390) I was surprised to find no mention of liq. ferr perchlor. fort. as a paint for the palliative treatment of ingrowin toe-nail. Since seeing it recommended in the *Journal* some year ago I have often used it with gratifying results. The paint is applie to the painful sulcus at frequent intervals, the nail is allowed t grow until the whole width can be cut with a concave edge instea of the usual convex, and tight shoes or tight shrunken socks carefully avoided. Some, who dread the small radical operation, appea to carry on thus for years.

The answer given to the seasickness question (Sept. 16, p. 391 also interested me, as there was no mention of bandaging. I hav spent some years at sea and under severe weather conditions hav suffered myself occasionally. In treating cases I have seldom foun any need for drugs if only a wide belt is *properly* applied. I use to bind my abdomen from below upwards with a wide flanne bandage as tightly as possible, and, to increase the resulting suppor to the viscera, I used to pack down inside the bandage one of th monthly magazines sometimes. It was rather uncomfortable, perhaps but that was far better than feeling seasick. The whole tip is to fi the viscera and blow the discomfort. One lady to whom I recommended this, who had been very seriously ill whenever she had had to make her frequent transatlantic crossings, and had always spen the whole time in her berth, told me that she was able to enjoy he subsequent voyages. Seeing that so many of our people have t make sea voyages in the Services just now, this simple method o dealing with mal-de-mer may be well worth recommending to them

Prefrontal Leucotomy

Dr. **BRIAN KIRMAN** (St. Mary Cray, Kent) writes: The statemen on prefrontal leucotomy and its performance on non-institutiona patients (Nov. 11, p. 650) is, I think, liable to misinterpretation We are informed, "Leucotomy should not be recommended wher patients occupy professional or highly responsible executive post if there is a reasonable chance of recovery without operation.' Surely if any patient, whatever his occupation, has a reasonabl chance of recovery without this hit-or-miss operation then he shoul not be operated on. Surely, in particular, it is important tha holders of responsible operative, as distinct from executive, post —e.g., engine-drivers—should not be given the "more irresponsibl attitude to life" which may follow the operation of leucotomy I find it difficult to believe that any patient can suffer from a depression so mild that he can continue outside a mental hospital an yet so severe and intractable that the drastic step of leucotomy i justified. Further, it will be admitted that the final decision in an case of mental disorder must be based on the patient's conduc rather than on his thought content. Particularly must this be s where the irrevocable step of leucotomy is contemplated. Yet i there not a grave risk that if the patient be not admitted to properly staffed psychiatric unit inadequate and unreliable information as to conduct may lead to inaccurate assessment and prognosis Finally, no mention is made in the answers which you publish o the legal complications that may develop as a result of an operation performed on a patient (though it be with his consent) o account of mental disorder, a patient who has not been admitte to any properly organized and approved psychiatric establishment The value of this operation in non-institutional cases is no established. The harm which it can do if inexpertly advised i incalculable. Under these circumstances is it not desirable at least t limit its use to patients in recognized psychiatric establishment until some more definite assessments of its results have been made

Atmospheric Pressure and Rheumatism

Dr. J. S. **ARCHIBALD** (British Columbia) writes: I have been looking over some back copies, and in your "Any Questions?" colum for March 4, 1944 (p. 347) I see where you failed to give an answe for the variation in rheumatic pains under different weather conditions. I have read recently that the low atmospheric pressure jus before a storm causes a swelling of the bodily tissues which irritate the nerves around an abnormal joint, the site of an old fracture etc. When the rain comes the pressure rises, with disappearance o the pain.

The Ophthalmoscope in Examining the Tongue

Dr. R. D. **LAWRENCE** (London, W.1) writes: Lacking an ordina torch and magnifying lens I recently used my ophthalmoscope wit a + 15 D. lens to inspect the papillae of a sore tongue. The goo light and high magnification (×18) give a most informative an gratifying view. Since then I have used it to examine rashes an other skin lesions. Perhaps this suggestion may help others.

Corrigendum

There were two errors in the heading to the article on "Chroni Intracerebral Haematomata" by Mr. Rowbotham and Dr. Ogilvi published last week at page 146. The second entry in the title shoul read: A. G. **OGILVIE**, M.D., M.R.C.P., Honorary Physician, Roya Victoria Infirmary, Newcastle upon Tyne.

INFLUENZA EPIDEMICS AND THE INFLUENZA VIRUSES*

BY

C. H. STUART-HARRIS, M.D., F.R.C.P.

Lieut.-Col., R.A.M.C.

LECTURE I

nfluenza virus A" is the name given by general consent orsfall *et al.*, 1940) to the virus originally discovered in 33 by Wilson Smith, Andrewes, and Laidlaw, who demon-ated that garglings from cases of human influenza would oduce a transmissible disease in the ferret. It has since en recovered in many different countries all over the world, d it is now known that there is a group of "A" viruses the ividual members of which differ in their antigenic structure t share certain characters; a serological relationship exists tween these viruses and the virus of swine influenza, dis-vered by Shope in 1931. Influenza virus B resembles virus A many of its properties, but is less pathogenic for the ferret d is absolutely distinct in antigenic make-up. The first us B strains (Lee and T.M.) were recovered almost simul-neously by Francis and Magill in 1940 in the United States, d, although only a few strains have yet been recovered, it already clear that a group of viruses exists as in the case of rus A, and that the individual members of the group are ore or less closely related to each other. No relation appar-ntly exists immunologically between the groups of A and B ruses.

Methods of Study of Human Influenza Virus Infection

The recovery of influenza viruses in the secretions from nose, roat, or lung, which succeeded well in the first few years after e discovery of virus A, has frequently failed in influenza out-eaks since then, and is not applicable to the majority of ses of virus B influenza. Nevertheless, methods based on covery of the virus are both convincing and essential to the udy of the antigenic make-up of the viruses concerned in fferent outbreaks, and ferret inoculation and observation main the classical method. Should inoculation fail to induce gns of infection in the ferret, the development of specific ntibodies may yet be observed and furnish useful confirma-ry evidence of infection in this animal (Horsfall *et al.*, 1940; uart-Harris, Glover, and Mills, 1943). Direct inoculation of ick embryos with filtered human garglings, though success-l in the U.S. and Australia, has largely failed in this country, ssibly owing to the effect on the embryos of wartime con-tions of poultry-raising. Indirect methods of demonstration f virus infection depend on the fact that a sharp increase in tre of antibodies occurs during the course of the illness as easured either by antibodies capable of neutralizing the athogenic effects of the virus or by complement fixation, or y antibodies capable of inhibiting red-cell agglutination by e virus in the test-tube. The latter method of Hirst (1942) now universally established as the most practicable means f examining large numbers of sera, and has given excellent sults even in the type of influenza most difficult to establish y direct methods—namely, influenza B (Stuart-Harris, Glover, nd Mills, 1943). The variable level of antibodies before the ccurrence of infection, and technical difficulties, make it essential that a simultaneous examination be made of two sera from each patient—one collected during the first few days of fever, and the second on the eighth to fourteenth day in convalescence. Most observers agree that if a fourfold or greater increase in titre of antibodies develops during the course of illness, influenza virus infection of the appropriate type may be presumed.

Influenza Epidemics in Great Britain from 1932 to 1944

The behaviour of influenza viruses in relation to human epidemics in this country has now been studied in varying degrees of detail over a period of 12 years, which included three years with major prevalences of influenza and four years of minor outbreaks. I shall refer to the Registrar-General's figures for notification of deaths from influenza in the 120-odd great towns of England and Wales with a population of over 50,000, partly because no figures are available for the incidence of simple influenza in the community, and partly because these statistics undoubtedly mirror the incidence of outbreaks in the population at large.

Chart I shows the weekly deaths throughout the year for the three seasons of 1933, 1937, and 1943 with major prevalences of influenza, and illustrates the remarkable similarity between them. These were the winters when influenza virus A was readily demonstrable in the throats of the victims by ferret inoculation and when strains of virus were subsequently established in the mouse with varying degrees of success. They were the winters when spreading epidemics of influenza occurred in all parts of the country and affected a considerable proportion of the population as well as the semi-isolated communities in which our studies were largely conducted. The British Institute of Public Opinion (1944) estimated that as many

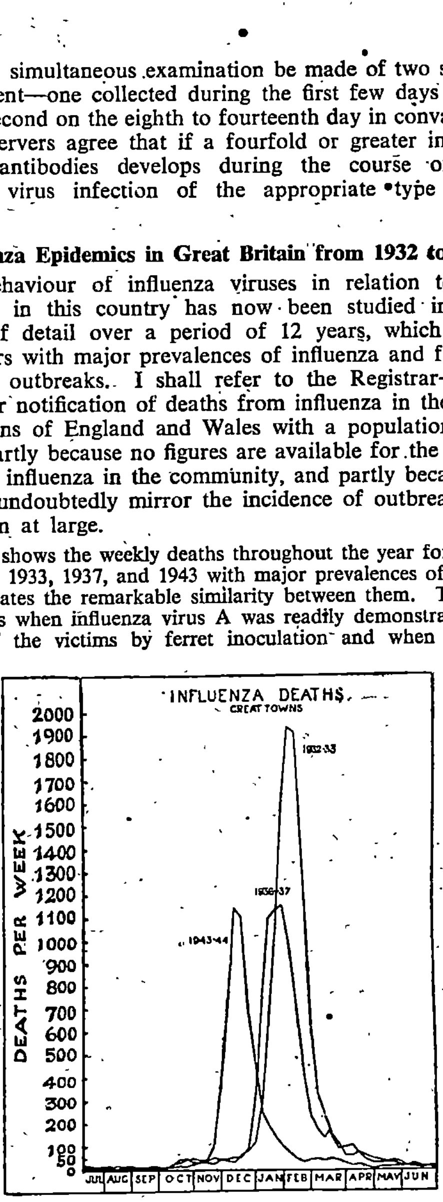

CHART I

---

* An abridgment of the Goulstonian Lectures delivered to the oyal College of Physicians on Jan. 16 and 18, 1945.

as 27% of individuals were confined to bed during the period of prevalence of the epidemic in the winter of 1943. Hoyle (1944) estimated, on the basis of complement-fixation studies, that during the same epidemic about 25% of the population were infected with virus A. We do not know the exact time-relationship between the peak of the outbreaks of uncomplicated influenza and the curve for death rates, but it seems probable that the former preceded the latter by two to three weeks in view of the lag between the onset of infection and death and the fact that deaths also occurred from post-influenzal pneumonia. Such an interval was found by Stocks (1944) when he compared the morbidity statistics for Service personnel admitted to E.M.S. hospitals with the curve for deaths for the whole country. The serological tests carried out in the years 1937 and 1943 indicated that at least 80%, and probably more, of the cases of influenza were associated with virus A activity, and no considerable residue of cases unassociated with this virus therefore occurred.

Chart II shows the four years 1934, 1936, 1938, 1942, and early part of 1943, when the notifications gave no indication of influenza outbreaks. In these years either influenza did not break out at all or else local prevalences which were mild and ill defined occurred. A solitary family outbreak in 1934 yielded virus A in the ferret. Several Service outbreaks in the spring of 1936 yielded no evidence of virus A, and were labelled "febrile catarrh" because of the clinical differences from the 1937 virus A cases. No outbreaks were reported in 1938 or in 1942, and in the latter year sporadic cases of clinical influenza in an Army garrison gave no serological changes either to virus A or to virus B. In Jan. and Feb., 1943, months when influenza deaths exceeded 100 in one week, a small increase in sporadic cases of influenza was encountered in two Home Divisions, and one unit experienced a small but explosive outbreak. We found serological evidence of virus B infection in these cases but failed to recover virus (Stansfeld and Stuart-Harris, 1943). The existence of virus B infection was also established serologically in sporadic cases of influenza in London and elsewhere, and Himmelweit established one strain in ferrets from a case of fatal pneumonia (Himmelweit, 1943). However, in this year some 50% of cases, many typical clinically of influenza, yielded no serological response either to virus A or to virus B. Later, in April, 1943, a small outbreak of influenza occurred in an Air Force establishment (Donnelly *et al.*, 1944), and in several scattered outbreaks in summer and autumn. Virus A infection was encountered in tests made at Hampstead (Andrewes and Glover, 1944) on sera from various parts of the country. In this year, therefore, first sporadic cases, then localized outbreaks, and finally a widespread epidemic of influenza A were all encountered.

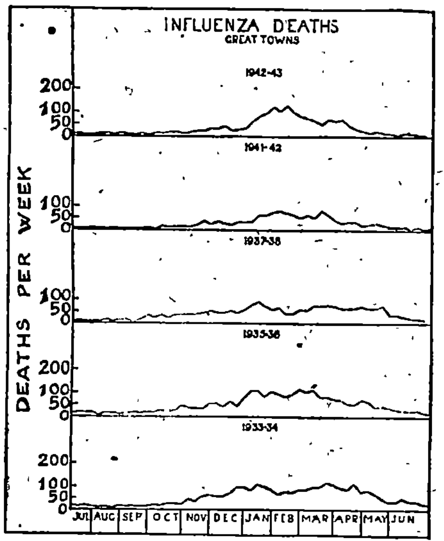

CHART II

Chart III shows the figures for the four intermediate years 1935, 1939, 1940, and 1941, when a sustained increase in incidence of deaths occurred between January and March each year yet no sharp peak developed. Localized outbreaks of influenza were recorded in each of these years, but the activity of the viruses was hard to understand. In 1935 two outbreaks in Army garrisons were investigated by Andrewes, Laidlaw, and Smith (1935). In January no virus A was detected in one barracks, yet it was readily recovered in the other in March. Some clinical differences between the cases in the two outbreaks were detected. In 1939 many outbreaks in schools and Service establishments were investigated. A few strains of virus A were recovered, but were difficult to establish in ferrets, and serum tests showed that only 30% of cases were infected with virus A (Stuart-Harris *et al.*, 1940). I could not distinguish cli ally between the virus A cases and the others in which infect by this virus was not demonstrable. Following the recovery virus B by Francis in 1940, the late Dora Lush retested some our 1939 sera against the virus B strain (Lush *et al.*, 1941) found several instances of undoubted virus B infection, yet forced to state that the majority of the sera yielded no bet evidence of virus B infection than they had of virus A. In year 1939, therefore, both virus A and B influenza had occurr

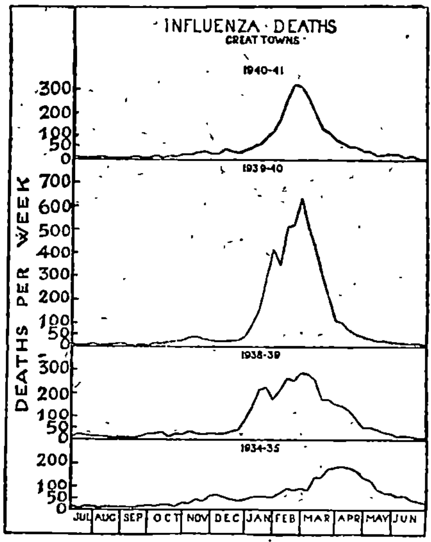

CHART III

but a large proportion of the cases were not demonstrably associa with either virus. Then in 1940, the spring following upon declaration of war, when mobilization for the Army and evacuati of children had occurred, an unexpected and relatively large w of influenza-like illnesses was encountered. Owing to the prev ing conditions, attempts to recover viruses directly were the o ones which were employed, and these all proved negative (Andre *et al.*, 1941). As no serological tests were made, the outbreaks this year remain of undetermined aetiology. The last year—t of 1941—will long be remembered by those of us who foolis imagined that we knew all about the causes of influenza epidem It was the winter of the aerial "blitz" on London and the la cities, and it was four years since the previous last widespr epidemic in 1937. When a group of cases in January in South England were found to be infected with virus A, and when the vi

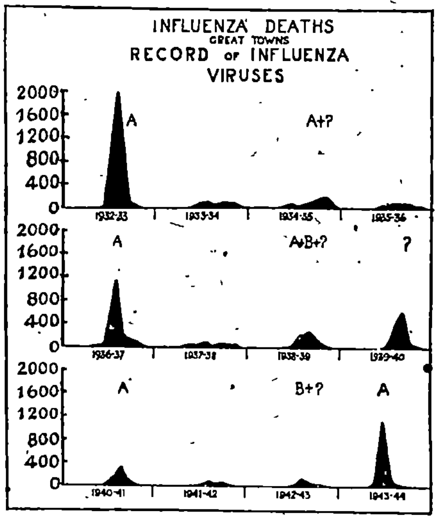

CHART IV

was recovered from garglings from a case of influenza in one of London shelters, it seemed probable that we were about to witn a serious epidemic. Our gloomy prophecy proved unjustified; spreading epidemic developed, and we were spared a disaster this most critical stage of our history. It is remarkable that chart for death rates showed clearly the small peak coinciding w the recovery of the virus in the laboratory. Nevertheless, the viru recovered in this year were characterized by their low pathogenic r the ferret, and, although no case yielded evidence of virus B ection, at least 20% of the sera tested this year had no evidence infection either by virus A or by virus B (Andrewes *et al.*, 1941). all four years, therefore, and in some of the years without peaks mortality, the minor influenza outbreaks were either A or B, or plus B, but, in any case, a proportion of cases, varying in number the different outbreaks, could not be typed. For these cases, ich appear to be neither A nor B, the name "influenza Y" has me into use (Rickard *et al.*, 1941). In these years the concatena- n of circumstances which is necessary for a spreading epidemic to velop—that is, the state of immunity of the population, the aracteristics of the viruses, and possibly other unknown factors— l not occur, and the virus outbreaks remained localized.

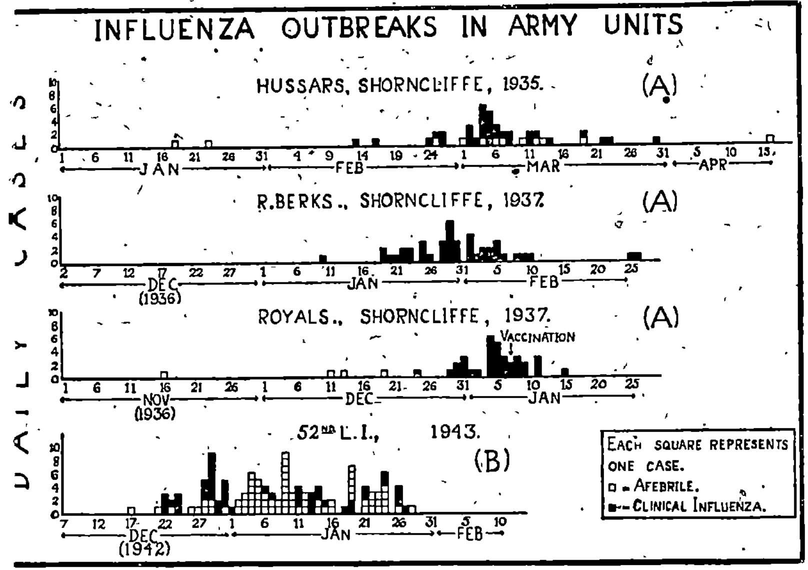

CHART V

Chart IV serves to recapitulate the experience with the viruses in ese 12 years and shows in semi-diagrammatic fashion the peaks of rtality from influenza. With the solitary exception of 1943, when ses of virus A influenza occurred in late spring and summer, the ords of virus detection in the laboratory which are indicated on chart represent the only direct evidence of virus activity in these ars in Great Britain. No evidence of virus activity or of the esence of virus has been found in between the winter seasons.

Epidemics in Other Countries

Comparison of the experience in Great itain with that in other countries where idies of influenza virus infection have been ade is essential in order to provide us th the proper perspective. Unfortunately, tailed studies have as yet been made in far o few countries for the picture to be anying like complete. Nevertheless, the fact clear that the majority of widespread idemics of influenza sweeping through tire countries or continents and causing a e in the death rate from pneumonia have en associated with virus A infection. Such ere the major American and Canadian idemics of 1937 and 1943, and the smaller evalences of 1935, 1939, and 1941. These idemics kept step remarkably with those corded in Great Britain, and Britain and e North American continent appear to form closely related epidemiological unit. The rus A outbreaks in Hungary in 1937 d 1939, though coinciding with outbreaks this country, varied in that much the ger wave occurred in 1939. Also, a widespread epidemic in ssia in 1936, when virus A was identified, occurred at a ne when there was no influenza A detectable here. Thus ere is some evidence that different parts of Europe expericed their major waves of virus A influenza at different times. gain, the Southern Hemisphere is completely out of step th the Northern Hemisphere. Melbourne experienced major waves of influenza in 1935, 1939, and 1942, and virus A infection was widespread in each of the latter two years. The Argentine had an outbreak of influenza A in 1940, and all these outbreaks in the Southern Hemisphere occurred at the coldest period of the year, between June and September.

Virus B appears to differ from virus A in that it is often not associated with large epidemics. Taylor and others (1942), in recording respiratory infection at a naval establishment in the Argentine, commented on the fact that influenza B occurred in 30% of cases in small waves scattered over several weeks. In Victoria sporadic cases of influenza B occurred in 1943 (Beveridge and Williams, 1944), and in Canada in 1943 was recorded a remarkably similar experience to that in this country, with evidence of 30% case incidence of influenza B in small prevalences in different parts of the Dominion (Hare, Stamatis, and Jackson, 1943). Nevertheless, the initial recovery of virus B was made in the Eastern United States in 1940 at a time when an influenza epidemic of some size was in progress, and outbreaks associated with virus B also affected California in 1936 and 1940 in widespread fashion. While virus B is thus more often than not associated with sporadic cases of influenza, it has at times been associated with large epidemics.

In addition to outbreaks when either virus A or virus B has been detected, various workers have recorded localized mixed outbreaks in which infection by either virus predominated but was accompanied by a variable proportion of sporadic cases due to the other virus. Such were the outbreaks in the United States and West Indies described by Lennette in 1940 and 1941. In these epidemics there were also some cases from which viruses were not recovered and which were unaccompanied by serological change to either virus. These remained in the unclassified group of influenza Y, whose percentage incidence varied widely. Even in the absence of an outbreak, sporadic cases of either influenza A or influenza B have been recorded from time to time. Workers in Australia (Beveridge and Williams, 1943) were particularly struck by the occurrence of sporadic cases of influenza A in 1943, when the incidence of total respiratory infections in various Army camps was too low to be described as epidemic. Sporadic A cases were also encountered in Canada (Hare, Hamilton, and Feasby, 1943) and in the United States (Salk, Menke, and Francis, 1944) in the spring of 1943. Such may merely have been the forerunners of a sequence of events preceding an actual epidemic, as in our own case in the same year, but it is clear that at

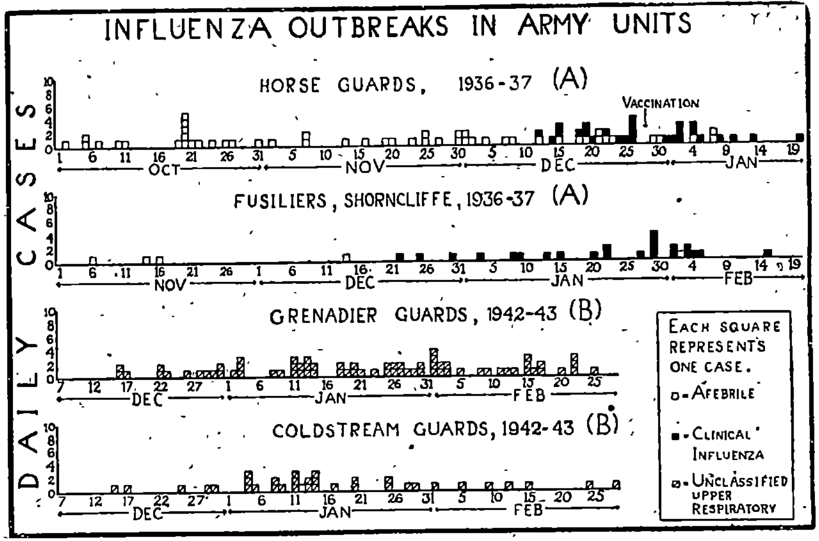

CHART VI

other times sporadic cases have not necessarily presaged an epidemic within a short period of time.

Form of the Influenza Outbreak

When the actual form of an outbreak of influenza in a semi-isolated community is studied, almost every conceivable variation is seen. Chart V shows the sharply peaked type of outbreak seen in regiments not subject to any considerable change of population. The first three of these outbreaks were due to virus A influenza in preponderance and affected 10 to 15% of those at risk, and a proportion of the cases in the fourth outbreak yielded virus B. The large number of afebrile cases in the latter epidemic was noteworthy, and altogether some 13% of the unit were affected. Both viruses have, however, been associated with straggling outbreaks even in the same years as those in which the sharply peaked outbreaks were encountered (Chart VI). The blame for such prolongation of the epidemic wave could not in these cases be laid upon considerable changes in the population at risk, but it is known from other studies that such changes do in fact exert a potent influence on the curve of the epidemic. Thus, in the Services, outbreaks of influenza provoke an unequal incidence of the disease upon the various members of the herd unit, those with lowest total service or shortest duration of residence in the herd being most affected. The accompanying Table shows the figures of incidence in Jan.–March, 1937, among men and boys at the Chatham Naval Barracks, when a high proportion of tests in the establishment and elsewhere showed virus A influenza. The recruits with less than 12 months' service suffered five times as heavily as the trained men with over 12 months' service. Similar results were seen at Shotley and Portsmouth Barracks, where trained men furnishing the ship's company had only one-fifth the amount of respiratory infection as had the boy seamen. It is tempting to relate the very high incidence in the boy seamen to the fact that in these establishments monthly intakes of raw recruits occurred and the boys spent only 9 months at each depot. Dudley (1926) has emphasized the paramount importance in droplet infection of the factor of rate of change of population, which is interlinked with the rate of addition of new members to the herd and the duration of residence of each member in the herd. Again, Topley (Greenwood *et al.*, 1936) showed in his experimental epidemics of mouse typhoid and pasteurellosis that without any change in virulence of the organism concerned, waves of renewed epidemic prevalence in the herd could be brought about merely by adding fresh uninfected susceptibles at a steady rate.

Table showing Incidence of Influenza during Epidemic of 1937 (January to March)

Establishment	Group	No. at Risk	Ages	Influenza (%)	Total Minor Resp. (%)
Chatham Naval Barracks	Recruits	1,440	18–20	12·7	28·2
	Trained men	5,731	18–20	3·8	5·6
Shotley, R.N.	Recruits (boys)	2,005	16	26·7	44·9
	Ship's company	471	—	7·9	10·1
Portsmouth, R.N.	Recruits (boys)	815	16	35·6	53·4
	Ship's company	277	—	6·5	11·9

It is in the Service training establishments that premonitory waves of the minor respiratory infections, which are always at a higher level than in the population at large, appear sometimes to lead up to actual epidemics of influenza. Possibly this is because the frequent population changes cause frequent interchange of respiratory pathogens and resultant increase in virulence of the agents concerned. Thus at Chatham, in 1936, a definite wave of some respiratory infection not associated with virus A preceded the January wave, when virus A was recovered. Also at the same barracks, in 1939, the January wave, which yielded neither virus A nor virus B, was succeeded after an interval of time by the occurrence of genuine cases of infection with both viruses. A Canadian camp near Toronto experienced three waves in the winter of 1942–3, of which the first was not associated with either A or B, the second consisted of some cases of B, and the third was of virus A influenza (Hare, Hamilton, and Feasby, 1943). Once, however, virus A has again become active, it does not follow that a general epidemic will result immediately, as shown by the recent experience last year. Although virus was then demonstrated in localized outbreaks in Canada, t U.S.A., and Great Britain in the spring of 1943, and in t last-named country a series of small outbreaks followed duri the summer, it was not until the autumn that conditions we ripe for the rapid wave of infection which characterizes a re epidemic of influenza, and this then occurred throughout t population.

This problem of the genesis of an influenza epidemic whi is linked with the mode of existence of the virus in betwe outbreaks has not been solved. There are four possible wa in which the virus could bridge the gap of its existence betwe epidemics.

First, it might exist by means of a continuous chain of outbrea so that always somewhere in the world there is an outbreak or series of sporadic cases which keeps the virus alive. The gene failure to demonstrate the virus in sporadic cases in non-epidem times must be taken into consideration here. Also, the remarka way in which over wide areas the viruses may suddenly beco active at almost exactly the same time, as happened in 1943, d not suggest that the epidemics in different countries arise by spre of infection from one country to the next. However, the study isolated communities, as at Spitsbergen or in Greenland, certai suggests that infection may at times be introduced from outside community and initiate an epidemic.

Secondly, the virus may live in the nose or throat of heal carriers in between outbreaks. It has certainly been demonstrated healthy carriers during an epidemic, and one outbreak of influenza in an isolated community in Alaska (Pettit, Mudd, and Pepp 1936) was traced to the arrival of three travellers, themsel unaffected, by 'plane from an area where an influenza epidem was in progress. Between outbreaks, however, the virus has n been found in healthy persons. Shortly before the war I began examine tonsils removed at operation from children. In this sm series of tests ferrets inoculated with emulsions of the glands fail to show evidence of virus infection. An enormous number of su tests would of course have to be made before negative results cou be considered significant.

Thirdly, the virus might transfer its activity to an animal h acting as a reservoir in between human epidemics. It is difficult know what animal might serve in this capacity, for ordina laboratory and domestic animals, with the exception of the pig, a not truly susceptible to the virus. In the pig, which has its o particular variety of influenza virus as parasite, the human influen virus A induces only a very mild disease (Shope and Francis, 193 The facts that cases of swine influenza in Great Britain have be found to yield strains of virus more closely related to virus A th to the American strain of swine virus (Glover and Andrewes, 194 and that Shope (1938) found serological evidence of natural inf tion of pigs with virus A during an outbreak of human influen may perhaps indicate that under certain conditions the hum influenza virus passes from man to the pig.

Fourthly, the virus might exist between epidemics in an unreco nizable form. Such a view was suggested by Andrewes (1942), w postulated the origin of influenza epidemics by the successive mu tion of grades of influenza virus. Andrewes thought that sporad human influenza might be due to a "basic" or rough form of vir devoid of its specific antigen, of animal pathogenicity, and of t power of producing the serological changes due to the norm antigen. This virus would certainly be undetectable by prese laboratory methods. Sudden mutation induced by frequent hum passages was thought to cause the transformation of basic vir into virus A or B, with characteristic antigen and animal path genicity.

Another unrecognizable form of influenza virus has in t analogous disease of swine been clearly demonstrated to the mode in which the virus persists between outbreaks. Sho (1941) has shown that in swine influenza the virus is alrea present in masked form in the pig's lung, attached to the lun worm which is such a frequent parasite of the pig. It appea that virus from pigs suffering from swine influenza passes the exterior via the ova of the lungworm, which are cough up, swallowed, and pass out in the faeces. The ova devel further into larvae in the earthworm, and when the latter a swallowed by pigs they develop by passing to the lung a are there established. They do not give rise to influenza once, but by some sort of trigger mechanism, such as chang meteorological conditions, or by artificial means such repeated intramuscular injection with *Haemophilus influenz suis*, the dormant virus is activated and the pig develo influenza. An analogous path to the tortuous progress fro pig to pig via the lungworm ova and the earthworm cou dly be conceivable in the case of human influenza, but the eral conception of a dormant phase of influenza virus mains as a possible explanation. Epidemics would then arise communities from virus already seeded but present in a eping phase, and would develop because of some changed nditions, perhaps of a meteorological nature, which released virus from its sleep and caused it to become active once ain. These, then, are the various possibilities, and more can- t be said as to which is nearest the truth. It must be mitted, however, not only that the solution of this problem a matter of academic interest but that it has important prac- al considerations.

Clinical Manifestations of Influenza Virus Infections

1. Influenza A

As a result of the correlated clinical and laboratory studies de in Britain during the 1937 epidemic (Stuart-Harris *et al.*, 38) it was thought that the infection produced by virus A ld vary from an extremely mild illness through increasing des of severity to a rapidly fatal pneumonia. It was also con- ered, as a result of observation of the sera of individuals in tact with cases of influenza but who did not themselves show nical signs of infection, that subclinical attacks were possible, d probably of frequent occurrence. The results of many dies by different observers all over the world since 1937 ve agreed with these views, though little fresh has been ded to the clinical data of infection during an epidemic embled in 1937. Study of the effects of deliberate infection human volunteers with virus A by Smorodintseff and others 37), by Burnet and Foley (1940), and by Henle, Henle, and kes (1942) has also strengthened the view that the virus is essential agent in the production of the clinical phenomena served during an epidemic. The cases which would be recog- ed by most clinicians as worthy of the diagnosis of influenza s appear to be merely infections of a particular degree of nical severity, and are almost certainly outnumbered during epidemic by subclinical infection and by other cases so mild to be clinically indistinguishable from endemic colds and minor maladies of the respiratory tract. Nevertheless, ups of uncomplicated cases of influenza due to virus A do nish a clinical picture whose recognition from one epidemic the next has been possible. The picture in the healthy dier with a typical attack of influenza is as follows:

The patient, usually in good health, is suddenly seized with a dache, and begins to feel shivery and ill. He sleeps poorly, king at intervals with a cough or with aching in the back or limbs, d in the morning is unfit for duty on account of weakness and er. He may feel dizzy on rising, may actually vomit or faint. e temperature is usually 100° at this time, and rises steadily to ° or 102° during the day, symptoms being at their height by the ning. Frontal headache, muscular pains, anorexia, drowsiness, and desire not to be disturbed are the chief symptoms, but a dry cough, cked nose, and perhaps sneezing indicate that the respiratory tract involved. The patient now has a rather characteristic appearance: face is flushed and slightly bloated, with circumoral pallor d slightly cyanosed lips; the eyes are glistening or slightly injected h excessive secretion and are in part concealed by the eyelids, ich droop a little. Apart from fever, and a normal or only slightly vated pulse rate, nothing much can be made out on physical mination. The tongue is coated with white fur; the nasopharynx dry, with dilated capillaries; and a rhonchus or group of rales may heard in the chest, particularly over the lung bases. The next y the temperature has fallen or has begun to fall, and the patient ls much improved. Cough, however, continues, perhaps with n in the region of the larynx or substernum. The throat may be e on swallowing and the nasopharyngeal adenoid tissue is swollen. the third morning there is often a renewal of fever and a return headache and muscular aching; cough continues, with production small pellets of mucoid or mucopurulent sputum; and the voice y be a little hoarse The lung bases may show patches of weak athing and fine rales, but percussion is not impaired, and a agram shows no abnormal shadows. Fever subsides after three five days, and the patient rapidly becomes convalescent, though h cough and slight sputum continuing, and perhaps a tendency instability of the temperature chart. The leucocyte count remains hin normal limits (4 to 14 thousand per c.mm.) throughout the ease, and the relative percentage of the various white cells is not normal. Post-influenzal debility and depression are not features convalescence in soldiers, who are usually fit for duty by the d of the week or the ninth day. Less fit subjects undoubtedly perience these sequelae, and the cough may also take longer to clear up than in fit men. Variations from this typical case, with onset following a premonitory cold, with frequent vomiting on the first day of illness, with more catarrhal symptoms such as acute coryza or a very sore throat, or aphonia, have been encountered, and the temperature chart varies widely. Afebrile cases and very trivial fevers are seen, and many of the 3–5-day fevers have diphasic curves. Prolonged cases of fever usually show persistent physical signs in the chest, and thus grade naturally into cases of influenza complicated by chest involvement. Such cases were divided by Scadding (1937) into three categories, and though his study was based on the civilian population, his findings agreed in the main with our own results on soldiers.

(i) The first group consisted of cases without clinical signs of lung involvement in which there was pharyngitis and tracheitis corresponding to the typical case just described.

(ii) The second group comprised cases with lung signs but without consolidation. These corresponded to cases with bronchitis and bronchiolitis which showed all the usual symptoms of influenza but in addition had areas of diminished movement, perhaps impaired percussion note, weak or suppressed breath sounds, and fine or medium rales scattered in patches usually at the lung bases. In spite of the abundance of physical signs in these patients, skiagrams of the chest showed only vague shadows, which were never as well defined as the clinician expected. It is presumably this type of case which is referred to by some as primary atypical pneumonia due to influenza virus. Apart from the fact that the majority of cases of atypical pneumonia as described in recent outbreaks (Dingle *et al.*, 1944) show *x*-ray abnormalities in excess of clinical expectations, most cases of influenza certainly do not exhibit abnormal *x*-ray appearances. The pathological lesion produced by influenza virus in experimental animals is essentially a necrosis of the epithelium of the finer bronchioles (Straub, 1937), and I would therefore suggest that the majority of the human cases of influenza belonging to this group probably have a bronchiolitis rather than a true involvement of the alveoli.

(iii) Cases with demonstrable consolidation furnished the most severe and also the most baffling of all the variations of the virus infection. The history was that either in continuity with the symptoms of influenza or more usually on the fourth or fifth day, or after a brief interval of a few days from the end of the attack of influenza, pain in the chest and increase in cough and expectoration heralded the development of a lung complication. The course of the pneumonia which followed was recognizably different from that of lobar pneumonia or, for that matter, from other forms of pneumococcal pneumonia. Though this is not the place to enter into detailed descriptions of resemblances and differences, it should be emphasized that the most fulminating cases seen in 1937 were essentially similar to the fulminating pneumonia of 1918 but occurred only rarely, and that a fatal pneumonia was chiefly limited in incidence to the very young and the very old.

The investigations which have thus so far been made on cases of influenza complicated by chest involvement have failed to elucidate the exact relationship of the virus to the pathological changes in the lung. The recovery of virus from cases of influenza with bronchiolitis proved consistent enough in 1937 to indicate that the virus infection coincided with the bronchiolar involvement. In cases of pneumonia, however, the virus was rarely recovered from garglings or sputum by the time that lung signs had developed, though it was recovered, in common with *Staphylococcus aureus*, from the lungs of three rapidly fatal cases (Stuart-Harris *et al.*, 1938). Also, some of the cases of pneumonia already had a high level of neutralizing antibodies in the serum by the time that pneumonia existed, which seemed to indicate that the virus infection often preceded the lung involvement. Hitherto, in this discussion, little attention has been paid to the role of bacteria in the production of disease during an epidemic. In swine influenza the virus alone produces only a mild disease, and simultaneous infection by the virus and the pig variety of *Haemophilus influenzae* is necessary for the full reproduction of the natural disease, which includes consolidation of the lungs. In human influenza the virus alone appears to be fully adequate to produce the uncomplicated disease, but the evidence favours the view that secondary bacterial invasion is necessary for pulmonary involvement, at any rate with the type of human virus known to us in the laboratory. The exact species of bacteria varies in different patients. The pneumococcus is far and away the commonest type to be found either in the pneumonia accompanying or in that which follows virus A influenza. The *Staphylococcus aureus* appears, however, to be particularly important in fulminating types of pneumonia, and a necrosing bronchiolitis and multiple abscess formation are found in such cases at necropsy (Scadding, 1938; Finland *et al.*, 1941). It may be that the rapidity with which patients with this type of pneumonia die favours recovery of virus from the lung, for fatal cases of pneumococcal pneumonia usually live longer than staphylococcal cases, and virus is not usually recovered from the lungs of pneumococcal cases at necropsy. Disappearance of virus from the lungs of ferrets also occurs at an early stage of infection, and by the sixth day, in spite of the presence of lung lesions, the virus may no longer be detectable by subinoculation to other ferrets. The haemolytic streptococcus has been extremely uncommon as a secondary invader of recent years, and the role of the *Haemophilus influenzae* in pulmonary cases has not been at all clear, although the organism has often been found in the sputum of all types of the disease. Thus it seems clear that the lung consolidations which have been encountered in recent epidemics have not been due to virus alone, although the virus is fully capable of producing lung lesions in the experimental animal and, in any case, may in some way destroy the defence mechanism against bacteria. The possible influence of bacterial infection on that due to the virus, by aiding spread of the virus in the lung, as suggested by Taylor (1941), must also be taken into account. It may be that the current strains of virus, as Burnet and Clark (1942) have suggested, limit their attack to the bronchioles of man, but that only a slight modification of their power of spread down the respiratory tract, with actual involvement of the alveoli, would be needed to enable them to produce a much more lethal type of disease. Meanwhile the remarkable way in which the curve of deaths from pneumonia follows the outbreak of the simple virus disease in the population must indicate an extremely close relationship between the virus and the pathological conditions in the lung, however these may be produced.

2. Influenza B

The only detailed studies of the clinical picture of influenza B which have been made agree in general in finding that there are few differences between the typical attacks of influenza B and those of A. Stansfeld and I in 1943 saw several groups of cases of influenza B and, both by the bedside and by retrospective analysis of symptoms and signs, were unable to differentiate the cases from those of influenza A seen in other years. The majority of the cases were febrile, and the same variation in duration of fever was seen as in influenza A. Cases complicated by lung involvement were not common, and skiagrams of the lungs of cases taken at an American Army laboratory were not abnormal. Other observers have reported a tendency for influenza B to be more insidious in onset than influenza A, often with a premonitory cold (Hare, Hamilton, and Feasby, 1943; Beveridge and Williams, 1944); and a greater tendency for the symptoms of an acute cold to accompany the fever was noted by Nigg and others (1942) in Minnesota and by Hare, Stamatis, and Jackson in 1943. Some afebrile cases with the same serological changes as febrile ones were encountered by Hare and co-workers in 1943. A number of cases seen by the latter were described as showing the *x*-ray findings of atypical pneumonia, but it seems possible that the high incidence of this syndrome may have been related to the occurrence of numbers of cases of atypical pneumonia in a respiratory wave preceding the occurrence of influenza B. In our own outbreak, cases of influenza B did not show the *x*-ray appearances of atypical pneumonia, and sporadic cases of the latter syndrome occurring at the same time of year as the influenza did not reveal serological changes of influenza virus infection. True consolidation of the lungs was not encountered by us during the prevalence of influenza B, but in the outbreak described by Nigg in 1942 a number of cases of pneumonia from which pneumococci were isolated occurred coincidently with the cases of influenza. Also, Himmelweit in 1943 recorded a fatal case of pneumonia in which the lung contained both virus B and enormous numbers of *Staph. aureus* at necropsy. It does seem probable, however, from the combined experience of influenza B in all parts of the world, that pneumonic complications occur less commonly than in influenza A. Evidence of subclinical infection during an outbreak of influenza B (Nigg *et al.*, 1942) has been obtained as in influenza A, and study of deliberate infection experiments in humans by Francis and others (1944) indicated that subclinical infection can indeed occur among the healthy contacts of individuals infected with the virus.

Differential Diagnosis of Virus Influenza, Sporadic Influen
and Influenza Y

It has been said that typical attacks of influenza A are rec
nizable clinically from one year to the next. Yet the variati
between the cases is so great that recognition of the disea
in the individual is impossible. Furthermore, if groups of cas
of sporadic influenza occurring in non-epidemic seasons at
times of the year and not demonstrably associated with eit
virus A or virus B are compared clinically with groups of vi
influenza, sharp distinction cannot be made (Rickard, Lennet
and Horsfall, 1940). Even during actual outbreaks many cas
are seen in which the diagnosis of influenza may be made
the bedside, yet no serological evidence of either virus A
virus B infection can be obtained and the viruses cannot
demonstrated in the human secretions. It is this group of cas
of clinical influenza referred to already as influenza Y whi
provides us with a still unsolved problem in aetiology. T
percentage of cases of influenza Y varies greatly in differe
outbreaks, being least in years of large-spreading outbreaks
influenza A and greatest in years of ill-defined outbreaks
influenza B or of mixed A and B infection. Stansfeld (19
attempted to differentiate the cases without serological chan
from the neighbouring cases of influenza B, and compared th
with the cases of influenza A which I had collected in vario
years. There were no sharp differences between the thi
groups, and this experience agrees with our own in 1939, w
the findings of Lennette (1941), of Taylor (1942), and of Ha
(1943). In 1943 influenza Y comprised some 43% of our cas
but 70% of influenza Y cases was found in outbreaks in Cana
(Hare, Stamatis, and Jackson, 1943) and in the Argenti
(Taylor *et al.*, 1942).

Although various observers have speculated on the aetiolo
of influenza Y, it is certain that we do not at present kn
the answer to this riddle. The various theories may be brie
mentioned. First, there is the obvious theory that these ca
are due to a third type of influenza virus so far undiscover
Secondly, influenza Y may be due to the basic form of influen
virus in its "rough" state without specific antigen, as pos
lated by Andrewes (1942). Thirdly, there is the theory t
these cases are really infections by either virus A or virus
but that for some reason there has been a failure of serologi
response, or that our methods are too crude to detect the ri
Evidence for this has been brought forward by Rickard a
others (1941), who found that cases of influenza Y possess
their sera in the acute stage of illness a higher content
neutralizing antibody to either virus A or virus B than cases
virus influenza in the same outbreak. It is known that
smallest proportional increase in antibody occurs among in
viduals with a high level of antibody before infection, a
therefore it is conceivable that such antibody increase as d
occur in the influenza Y cases is undetectable by our pres
crude methods. Francis (1944) also encountered cases of inf
tion following deliberate instillation of virus B in which,
spite of a good clinical reaction, serological change was tri
or absent and the virus was not recovered from garglin
Another possibility is that these cases are due to antigenica
different strains of the same A or B virus. Magill and S
(1944) have pointed out that if a large number of differ
strains, especially of viruses isolated during an outbreak,
employed in the tests of sera from the same outbreak m
cases will be found to show antibody response to at least o
strain than if only one strain is used in the test. My perso
view would incline me to the belief that another virus,
other viruses, as yet unknown, are the cause of at least so
of the influenza Y cases in an outbreak. It would seem lo
cal that if virus B differs from virus A in being much l
pathogenic for the ferret, other viruses capable of produci
influenza in man exist which are still less pathogenic for
ferret than virus B. The antibody estimations carried out
the cases of influenza Y by us (Stuart-Harris, Glover, and Mi
1943) showed these cases to occur slightly more often amo
the groups with high initial antibodies to virus B (Chart V
Cases did occur with all grades of B antibody, however. T
influenza Y cases were also distributed in time throughout
epidemic, though with less incidence in the first two weeks
January, when virus B infection was relatively common
Until some method is found of recovering virus from th

individuals, however, the aetiology of influenza Y must remain undecided.

Certain Other Respiratory Diseases Unrelated to Influenza Virus Infection

Francis, in an address in 1937, when discussing the differential diagnosis of influenza said it was easier to describe what influenza was not than to define what it was. This point of view certainly appeals to me, and one seems to be on reasonably certain ground in stating that influenza is not the endemic afebrile cold, is not streptococcal tonsillitis, and is not primary atypical pneumonia. Nor, in recent years at any rate, has it been a gastro-intestinal disease. However, it is certainly true that during an epidemic both influenza A and influenza B can mimic the common cold, and one feels that the common cold virus will eventually be found to be related to the group of influenza viruses and that at times it may cause attacks of clinical influenza. More cannot be said in the absence of knowledge of the antigenic make-up of the common cold virus or until some more reasonable way is found of working with the virus than by studying its effect in the chimpanzee (Dochez *et al.*, 1930). Streptococcal tonsillitis stands more clearly apart from influenza than any of the conditions previously discussed, but there are some cases of exudative tonsillitis in which the haemolytic streptococcus is not concerned that may occur side by side with other cases more clearly resembling clinical influenza. The febrile sore throat or pharyngitis of the medical inspection room does not seem to be influenza, and yet may at times be extremely difficult to distinguish from it. There is a greater tendency for pharyngitis to be accompanied by severe laryngitis and tracheitis, and the name, "febrile catarrh," though now discarded, may yet be found to be of use when our knowledge of the virus and bacterial infections of the upper respiratory tract is more complete. The group labelled 'primary atypical pneumonia" includes examples of infection by viruses of the psittacosis group (Meiklejohn *et al.*, 1944), but a majority of the cases are of undetermined aetiology.

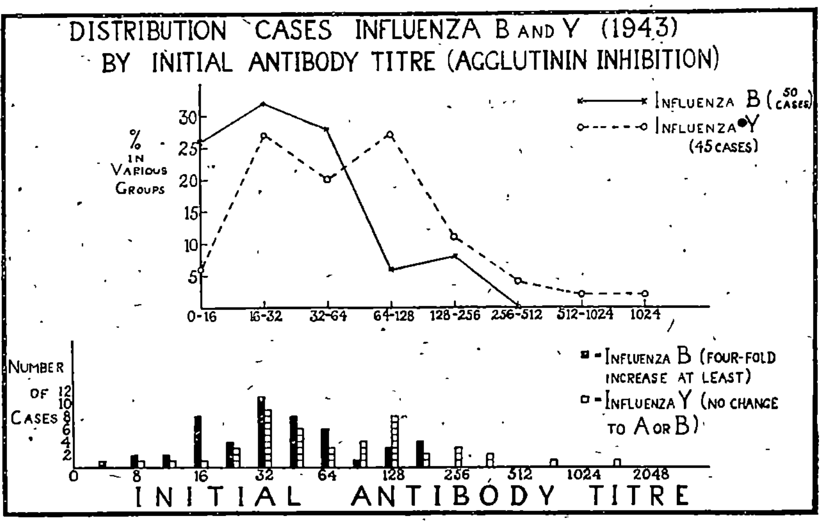

CHART VII

On purely clinical grounds, atypical pneumonia is readily confused with influenza in view of the occurrence of fever, constitutional symptoms, and signs of respiratory-tract infection in both conditions. The onset is more often insidious, the fever lasts longer on the average, and the cough is more often paroxysmal, irritating, and accompanied by substernal discomfort in the case of atypical pneumonia. The characteristic veiled shadows spreading out from the hilar regions which are seen in skiagrams of the chest in atypical pneumonia at once distinguish the condition from simple influenza. Also, the fact that there is more to see in the *x*-ray picture than one would expect from examination of the chest should help to differentiate atypical pneumonia from influenza with bronchiolitis. The discovery of the rise in titre of cold agglutinins for human red cells (Peterson, Ham, and Finland, 1943) which occurs in the serum of many cases of atypical pneumonia during convalescence may be of use when the serological tests for influenza cannot be applied. Further clarification and definition of the atypical pneumonia syndrome from influenza must, however, await, as in the common cold, exact knowledge of the aetiology of the condition. The studies of Eaton *et al.* (1944) on the pulmonary disease in cotton-rats and hamsters induced by sputum from cases of atypical pneumonia deserve special mention in this connexion. In the meantime, the careful studies in progress in the United States (Commission on Acute Respiratory Diseases, U.S. Army, 1944) have led to a recognition of the commonness of the disease, its high incidence in Army recruits, and its almost constant ratio of 10% of the total undifferentiated minor maladies of the respiratory tract in Service personnel.

The Possible Relation between Virus Influenza and Pandemic Influenza

I cannot conclude without a few remarks on the possible relationship between influenza epidemics such as those which I have described and the type of influenza responsible for the 1918 pandemic. Dwight O'Hara (1944) has recently suggested that we owe our present freedom from devastating influenza epidemics to the annual or biennial recurrence of fair-sized outbreaks. A mere glance at the incidence of influenza since the middle of last century is enough to give a bold negative to this theory. The freedom from influenza which prevailed for nearly 50 years after 1847 was, it is true, followed by the pandemic of 1890. But ever after this we have experienced a much greater prevalence of the disease than before 1890, and experience in distant parts of the world, such as Australia, has been much the same. The wartime years which preceded the 1918 wave, far from being years of low prevalence of influenza, were actually periods in which pneumonia mortality and respiratory infections in general increased steadily each year. In the present war, and in spite of unprecedented overcrowding and movement of population within this country, the epidemics have been, if anything, milder than in pre-war years, and there is no suggestion that we are likely to experience the return of a pandemic such as that of 1918. Abler workers than I have speculated upon the relationship between influenza viruses and pandemic influenza, and Burnet and Clark (1942) have given an admirable survey of the possibilities. Analogy between virus A influenza and the pandemic variety breaks down even if only the mild summer wave is considered. For though the three-day fever of June, 1918, was very similar clinically to virus A influenza, the occurrence of a much higher mortality in the young adult of 20 to 30 even in the first wave in 1918 indicates some fundamental difference. The later waves in 1918 not only showed the same trend in age mortality as did the first wave but suffered an incidence of pneumonia of a size entirely unlike present-day experience.

Three main explanations have been advanced to account for the different characteristics of the 1918 pandemic. First, it may have been due to a virus of entirely novel antigenic type which, meeting a wartime and susceptible population, behaved as, for instance, measles behaves in a virgin population not previously exposed to it (Fiji, Faröe, and St. Helena epidemics). The suggestion made by Laidlaw and supported by Shope was that the swine influenza virus now prevalent in the pigs of the Middle West of the United States represents the survival in an animal host of the pandemic human virus (Shope, 1943). Evidence for this is simply that swine influenza first occurred in the United States in 1918, and Koen suggested at that time that it was acquired from human cases. The occurrence of antibodies to swine virus in the sera of adult humans but not of children was at one time thought to favour this view, but it is now known that such antibodies develop in response to infection by human virus A influenza. Secondly, pandemic influenza may have been due to a peculiarly high rate of secondary bacterial invasion. Evidence both for and against this can be assembled, but perhaps the weight of argument is against this theory, because no one type of bacterial species occurred more frequently than any other. The third view, is that the virus of 1918 influenza was of the same antigenic character as, for instance, virus A, but possessed unique biological properties (Burnet and Clark, 1942). Andrewes (1942) conceived of pandemic virus as being merely a more advanced grade from the virus of present experience with the added property of attacking the lung, but felt that antigenic mutation would alone explain the lethal effect of the viruses on the young adult. Burnet and Clark explain the latter phenomenon on the basis of excessive reaction of the inflammatory response to a strain of virus capable of spreading down into the alveoli.

Comparison of the properties of the various influenza A viruses encountered in the epidemics of different years certainly supports the view that virus strains of almost the same antigenic constitution can vary considerably in their virulence for experimental animals. It is a striking fact that whenever a considerable epidemic is under way no one seems to find it difficult to establish strains of virus A in the ferret, the clinical responses in the ferret are clear-cut, and passage is successful in a high proportion of instances. The viruses obtained from localized outbreaks of years such as 1939 and 1941 were by contrast difficult to transmit to ferrets, caused poor clinical reactions, and tended to die out on passage unless "nursed" along. We also know something of the variations which can be induced in the virus by simple transfer from one animal to another, so that the virus appears to be biologically plastic and capable of very considerable modification. The studies of Burnet and Bull (1943) on the changes which occur in the influenza virus immediately after isolation from human cases indicate the relative instability of the human virus and the considerable ease with which mutation can be induced. Should a strain of virus arise in nature, as a result, perhaps, of a particular combination of circumstances, which possessed both heightened power of spread and changed antigenicity, then a pandemic with particular mortality in the younger age groups might result. When all is said, however, our theories must remain unproved in the absence of opportunity of putting them to the test, and everyone must agree that ignorance is a more blessed state than knowledge born only of bitter experience of a new pandemic.

To summarize: I have tried to show how the knowledge of the virus agents active in the causation of influenza has begun to illuminate the problem of one of man's most implacable enemies. Whenever the influenza epidemics of recent years in Great Britain have been intense and widely spread they have been associated with that virus designated influenza A. Intervening epidemics have been associated both with virus A and with virus B, but a varying proportion of cases clinically similar to those associated with these viruses have remained of unknown aetiology. The clinical features of infection by the two known groups of influenza viruses have been described, and an attempt has been made to interpret the role of the virus in the pathogenesis of the human disease. The manner in which knowledge of the influenza viruses may help us to interpret pandemic influenza of the type experienced in 1918 has been briefly described, and emphasis has been placed on the variable biological properties of the different virus strains and on their power of rapid modification.

We have received from the librarian of the U.S. Office of War Information, American Embassy (1, Grosvenor Square, W.) the printed report of a discussion on "Putting the Disabled Veteran back to Work." Those who took part included Dr. C. D. Selby, medical consultant, General Motors Corporation, and Dr. Harley L. Krieger, medical director, Ford Motor Company. The debate was held in the Mellon Institute on the occasion of the eighth annual meeting of the Industrial Hygiene Foundation, and the report is published by that body from 4400, Fifth Avenue, Pittsburgh, Pennsylvania. It forms Bulletin No. 2 of the Foundation's special series of publications.

DRYING PENICILLIN BY SUBLIMATION I THE UNITED STATES AND CANADA

BY

EARL W. FLOSDORF, Ph.D.

Assistant Professor of Bacteriology, University of Pennsylvania, an Director of Research at the F. J. Stokes Machine Company

Desiccation from the frozen state has now become well know as the result of its very wide and extensive application to th drying of blood plasma. The art itself is old, and dates bac to Shackell in 1909. The subsequent history of the development of desiccation from the frozen state during the preser century has been recorded in previous publications (Flosdor and Mudd, 1935; Strumia *et al.*, 1941; Flosdorf *et al.*, 1945 and these include also reference to the work of Shackell (1909 Harris and Shackell (1911), Hammer (1911), Rogers (1914 Swift (1921), Sawyer *et al.* (1929), Elser *et al.* (1935), Reiche Masucci, McAlpine, and Boyer (unpublished; see Flosdorf an Mudd, 1935), Reichel (1939), Greaves and Adair (1939), an Greaves (1942, 1944).

By 1935, as a result of the development made by thes various workers and of our own contributions (Flosdorf an Mudd, 1935), desiccation from the frozen state was availabl for general production of various biological products. Henc when the war came the art had been developed and was read for use with blood plasma; of course, under the stimulatio of a project like this, the process was soon applied on grander scale than ever before.

Earlier efforts to evaluate the possible clinical usefulness o penicillin were abandoned because its liability seemed to mak it unsuited as a therapeutic agent (Clutterbuck *et al.*, 1932 However, when later research had resulted in demonstration o the effectiveness of penicillin (Chain *et al.*, 1940; Abrahar *et al.*, 1941), it was natural that desiccation from the froze state should be called upon to stabilize it; meanwhile, dryin this way had undergone the necessary development. In man respects the problems with plasma and penicillin were simila and parts of equipment even identical. On the other han certain peculiarities in the nature of penicillin introduced problems quite different from any encountered earlier.

Actually, solutions of penicillin are not so labile that the cannot be evaporated at about room temperature without los in potency, but they foam badly. Desiccation from the froze state avoided this problem. This also allowed a more highl soluble product to be obtained.

On the other hand, if penicillin is to be dried while froze it is necessary to hold the temperature lower even than tha which is required for many other biological products, includin blood plasma. This is not because of the biological labilit but because of physical characteristics. Penicillin does no remain in a completely unsoftened condition unless the temperature is below about −20° C., and preferably below −25° C The exact temperature varies somewhat with the degree o purification and with the concentration of the product; nevertheless, even the least exacting of preparations require a lowe temperature than plasma. If penicillin is not kept at suc low temperature, because of softening there is bubbling an frothing to a partial extent, and this is sufficient to introduc problems of practical control which are difficult to overcome Consequently, it is simpler to maintain a lower temperature.

Drying in Bulk or in Ampoules and Bottles

Drying of a biological product intended for parenteral injection may be carried out either in bulk or in the final containe in which the product is to be stored and distributed. However, drying in bulk has not met with general favour becaus of the obvious problems of maintenance of sterility in subdividing dry powder into ampoules for distribution. The problem is made more difficult because of the hygroscopic natur of dry penicillin, the size of doses requiring accurate weighin of small quantities. In spite of this, attempts were made t dry penicillin in bulk for transfer of dried powder to fina ampoules, and these represent the first time this has ever bee tried in routine large *production* of a biological produc To-day, however, the trend has returned to one of drying i the final container as proposed in 1935 (Flosdorf and Mudd, 935). In some cases preconcentration in bulk by partial dryng from the frozen state is used with transfer of concentrated liquid to ampoules for final drying. This reduces the size of the final ampoule required, particularly where the original peniillin solution is very dilute. Concentrating in bulk in this way oes not offer the same problems of sterility as are encountered y complete drying in bulk, inasmuch as a representative sample f the concentrated liquid is readily enough obtained for baceriological culturing. If it is found sterile, then there is reasonble assurance that the entire batch is sterile, in contrast with he ineffectiveness of proper bacteriological sampling of dry owders. Improvements in the process of extraction now permit production of concentrated solutions without evaporative oncentration.

If final containers such as ampoules or bottles are used for rying, close attention must be given to the necks selected, so hat they are adequate in size for the escape of the vapours. hese conditions have been fully described (Flosdorf and Mudd, 935).

Freezing Conditions

There are no particular limitations with regard to the temperatures for freezing other than that they be low enough to nsure complete solidification and fast enough to avoid partial eparation of concentrated penicillin. As indicated above, temperatures of −20° and −25° C. represent the maximum which an be used if an unsoftened product is to be dried.

There is a further complication involved in large-scale production of penicillin in contrast with plasma. Because of the larger bulk of material in a single bottle in the case of plasma, he contents will not thaw quite so quickly when removed om the freezing-bath. With penicillin the amounts are so nall in the individual containers that this is not the case. Unless special precautions are taken there is considerable hazard of partial thawing after removal from the freezing-bath or om the frozen storage vaults. This is during the loading of he drying chambers and during evacuation to pressures that nable the frozen state to be maintained by evaporative coolng. For that reason, drying chambers of the type used widely or blood plasma (Flosdorf *et al.*, 1945) have been modified to he extent that they can be chilled to sub-freezing temperatures. he product, after being loaded into the chambers, is held in a ozen condition in this way until the proper degree of vacuum obtained. Then the chilling medium is removed from the ckets of the chambers and the heating medium circulated at proper temperature.

A still simpler procedure has now been introduced which greatly reduces the labour of handling the bottles. The bottles ontaining the penicillin as liquid are introduced into the chilled rying chambers. As soon as the penicillin has been frozen, hich may be within as little as half an hour, the chamber is vacuated and then heated in the usual fashion.

Vacuum Conditions for Drying

It is necessary to set up conditions of vacuum whereby most of the air is removed from the system; otherwise the drying ould take an impossibly long time. Under these conditions he ice in the product evaporates directly to the vapour phase.

The water vapour which evaporates from the frozen product may be removed by a number of means, but, in large prouction, only two basically different methods are being used. ither the water vapour is pumped directly by means of large eam ejector pumps (Flosdorf *et al.*, 1945; Flosdorf and Stokes, 941) or, alternatively, large refrigerated condensers are used combination with mechanical vacuum pumps. In the latter case the condenser removes the water vapour and the mechanil pumps serve principally to keep the air out of the system. hemical desiccants or adsorbents may also be used in place of he refrigerated condensers, but these have not been employed n a production scale for penicillin except in certain combinaons with other equipment which will be discussed below.

In any event it is necessary by means of the direct pumping stem or the refrigerated condenser to set up a partial presure of water vapour below that of the penicillin at the temerature at which it is being dried. For temperatures of 20° to −25° C. this means a vapour pressure of the order of 500 to 750 μ. Consequently, the steam ejector or condenser must produce pressures below this, and, on the surface of things, one might expect that the lower the temperature produced by the condenser or the higher the degree of vacuum produced by the steam ejector the more rapidly drying would proceed. However, this is not the case. As drying proceeds the receding surface of the layer of ice within the penicillin becomes covered with a porous outer layer of dried material, which means that the vapours must escape through orifices. According to the laws of adiabatic gaseous flow through orifices—the Napier equation—a pressure of water vapour produced by the condenser or by the steam ejector which is 55% of the vapour pressure of the penicillin will result in as rapid drying as can be obtained (Flosdorf *et al.*, 1945). This we have confirmed by experiment, and it means in effect that a degree of vacuum of the order of 250 to 400 μ is adequate. This applies only to the first stage of drying from the frozen state, which is in reality a process of sublimation of the ice contained in the product. Nevertheless, this does cover the removal of most of the moisture.

However, after all of the ice has been removed from the penicillin we have the second stage of drying, which is one of removing the final traces of moisture from the dry product. The hygroscopicity or the vapour pressure of the dry penicillin varies widely with the preparation in question and depends, among other things, on the degree of purification and concentration. This vapour pressure of the final dry product determines the final degree of vacuum which is required; generally it has been found that from 50 to 100 μ is sufficient.

One procedure which has met with some favour is to use steam ejectors or refrigerated condensers in the first stage of drying for removal of the bulk of the water vapour from the frozen penicillin solution. This affords the most economical way of carrying out the process, since a vacuum of no better than 250 μ is required. To complete the drying, a chemical desiccant is used. By choice of the proper one, partial pressures of water vapour as low as a fraction of a micron are readily obtainable, and make it possible to reduce the final content of moisture in penicillin to as low a level as needed (Flosdorf *et al.*, 1945). Inasmuch as the amount of actual water to be taken up by the desiccant in this second stage is small, weights of desiccant which are reasonable will last for a long time before replacement or regeneration is necessary.

As an aid in reduction to proper final content of moisture the temperature of the penicillin may be raised towards the end of drying to increase the vapour pressure. This in turn raises the pressure which it is possible to use for obtaining final dryness. Although originally it had not been considered safe to take the final dry penicillin to above 40° C., there seems now to be evidence that the final product may be taken to considerably higher temperatures—even as high as 110° C. This, of course, simplifies the problem of obtaining low final moisture.

Final Degree of Moisture and Stability

Although exhaustive data are not yet available which relate the stability of penicillin at various temperatures to the actual content of moisture in the dry product (among other things, it varies with the degree of purification), it is generally agreed that the lower the content of moisture the greater the stability. There is considerable difference of opinion as to just what is the critical level, in some quarters this being placed as high as 7%. In the United States it is required by regulation that the product be reduced to below 2.5%, and there is some evidence that a final content of moisture of 0.5% is necessary for *maximal* stability.

Sealing of the Final Container

Obviously, if it is important to bring the content of moisture in the penicillin to a low point in the first place, it should be maintained low. A glass-sealed ampoule is always of first choice for a hermetically sealed container, but it does offer some difficulty in the clinical use of the material. For this reason bottles sealed with rubber stoppers have met with favour. When rubber-sealed bottles are used, however, it is necessary to relate the length of time the penicillin remains fully potent to the effectiveness of means of protection of the rubber stopper. Rubber and synthetic products are permeable to moisture. In the case of products like plasma this is not significant, but with others which have a low content of solids it is highly important to give consideration to the amount of moisture going through the stopper.

For example, compare a 10-ml. amount of serum with a 300-ml. amount of plasma. If, under certain conditions of long storage, the 10 ml. of serum will be taken up to 8% moisture content, the 300-ml. amount of plasma will have its moisture content increased only by one-thirtieth of this—by about 0.27%. The reason is that there are 30 times as much solid matter by weight in the plasma container as in the small serum container, yet the amount of moisture permeating the stopper is the same. With penicillin, where the amount of solids may be only one-fifth as great as even in the 10-ml. quantity of serum, the moisture content could go as high as 40% (Flosdorf *et al.*, 1945).

Other Methods of Drying

As indicated above, the stability of penicillin is such that it may be evaporated as a liquid at room temperature without undue loss of potency. Recently, preconcentrating dilute penicillin solution in bulk by means of dielectric heating in low-vacuum apparatus has been carried out successfully. This reduces appreciably the load on the equipment for final desiccation from the frozen state, particularly if the original penicillin solutions are quite dilute. After preconcentrating in bulk in this fashion, the liquid product is distributed to phials in which the concentrated penicillin is frozen and then dried by sublimation.

It may be that before long it will be possible to dry the concentrated solutions of penicillin as a second step by means of dielectric heating on a practicable basis in the final ampoules. The reduction to a final moisture content of 0.5% must be accomplished as a third step in which a warm bath is used to heat, since the dielectric means become ineffective on the dry penicillin. The final product is less attractive in appearance. Solubility is slower, but fast enough for the purpose. The matter will then resolve itself simply into one of economy in handling a large number of ampoules in the second and third steps required with dielectric heating as compared with drying by sublimation.

Summary

Problems met in drying penicillin in contrast with those with blood plasma and other products are discussed. Procedures used in large production are described. Final moisture requirements and types of containers suitable for penicillin are discussed. Use of dielectric heating of penicillin is considered.

The Research Board for the Correlation of Medical Science and Physical Education, which was formed in 1943 under the chairmanship of Brig. F. Howitt, has issued a first interim report. The material is arranged in four chapters, on maternity and child welfare, education and recreation, the Services (the normal recruit, the substandard recruit, and the sick, injured, and disabled), and a note on the work of the Industry Subcommittee by Brig. F. A. E. Crew. There is a foreword by the chairman, and the report concludes with some recommendations. Copies may be obtained from the Ling Physical Education Association, Hamilton House, Bidborough Street, W.C.1, price 2s. (postage 3d.).

GAS GANGRENE AFTER SECONDARY SUTURE OF SHELL WOUND OF THIGH

BY

J. HAMILTON BARCLAY, M.D., M.S., F.R.C.S.
Senior Honorary Surgeon, Royal Victoria Infirmary, Newcastle-upon-Tyne; Professor of Surgery, University of Durham

I am led to report this case for two reasons: (1) the fact tha the gas gangrene followed secondary suture of the shell woun of the thigh; and (2) the fact that the patient recovered afte apparently being moribund.

The former occurrence was most disconcerting, as the patier was very fit before the operation and, clinically, the woun looked healthy and suitable for suture and the swab was steril Many cases of gunshot wounds had been submitted to secondar suture, and this was the only one which caused any anxiety- all the others were successful. But it is important t record failures or accidents as well as successes. And, a Sir Ernest Rock Carling, with whom I have been in communica tion, remarks, "one accident does not vitiate the principle, an secondary suture is extremely important." It emphasizes th necessity for taking swabs not only from the surface bu from the recesses of the wound. Apparently the organism had been lurking just beneath the surface.

With regard to the latter occurrence, I have never i all my experience seen a patient so ill recover. I aske Prof. F. C. Pybus to see him with me, and we both agree there was no chance of recovery. It shows that "where ther is life there is hope."

Case History

On June 23, 1944, Capt. X., aged 30, and the crews of two tan were resting beside their vehicles when a German shell burst ne them, wounding seven men, including the captain. Assisted b another officer, he dragged the wounded men into slit-trenches, whic were dug in the well-cultivated orchard of a French peasan Capt. X. forgot to apply his field dressing to his wound, whic became contaminated with soil. An hour after the bursting of th shell he was admitted to the regimental aid post with a lacerat wound of the skin and muscles of the right thigh, on its anteri aspect, the wound being about 4½ in. long by 2 in. wide. At No. Casualty Clearing Station later that day the wound was found be widely open but not suitable for surgical treatment, so it w dressed with sulphanilamide powder and vaselined gauze, and a ba splint was applied. Two days later, in hospital, the splint w removed, as it was causing pain, and the wound was re-dresse The patient's general condition was very good. Between the 23 and 29th he received 3 c.cm. of A.T.S. and 20 g. of sulphanilamid

On the 29th he was admitted to the Royal Victoria Infirmar Newcastle-upon-Tyne, under my care. His general condition w still good. The wound of the thigh was rather dirty and poutin and of a greenish colour. A swab was taken from the wound, ar this produced cultures of mixed penicillin-sensitive organisms. Tw days later another swab showed streptococci suitable for penicill treatment. The patient complained of pain on micturition ar frequency but no discharge.

On July 6 the wound was cleaner, and not everted so muc There was a very scanty colourless exudate. Dressing was done wi penicillin powder and tulle gras, and the wound became cleaner ar healthy-looking. A swab showed it to be sterile, so it was decid to carry out secondary suture. This was done on July 14, the edg being undermined and the skin approximated with silkworm-g sutures. Proflavine and sulphanilamide powder were dusted in the wound. Next day there was a slight amount of serum oozi from the lower part of the wound.

On the 16th there was slight tenderness round the wound; sor blood-clot was oozing, and this reappeared when cleared away. H pulse was 120, his temperature normal, and he was fairly comfo able. Some sutures were removed. By the next day a large amou of clot was escaping from the wound. The remaining sutures we removed and masses of foul-smelling clot evacuated. There w oedema over the knee and thigh, and the leg was very tender. H pulse was 108 and temperature 99° F. He was in pain and look ill. A few bubbles of gas escaped from the wound. An intr muscular penicillin drip was set up in the left thigh. Sulphathiaz was given, together with 12,000 units of anti-*Cl.-welchii* seru intravenously. That evening 22,500 units of polyvalent serum we administered. A blood drip was started at 09.30 hours, but 10.30 hours a severe reaction to the A.G.G.S. took place, characte ized by respiratory distress, vomiting, and urticaria. The blood di was stopped as a precaution. The patient was gravely ill the who day. A swab showed the presence of clostridia other than *welch* with sensitive *Staph. albus* and resistant faecal streptococci.

The next day (the 18th) he was still very gravely ill, his tempera- e being down to 95° F. and his pulse up to 150, thready and ely palpable He vomited altered blood, the vomiting being ortless. A duodenal tube was passed and was left *in situ*. The tput of urine fell almost to zero, and he was pale, grey, and ating, and looked like dying. The oedema had spread up from thigh on to the abdomen, back, and lower part of chest. In evening, as a last resort, multiple incisions were made in the gh, back, and abdominal and chest walls. Considerable quanti- s of serum and a little gas escaped. A saline-sulphathiazole drip s started—3/4 pint in four hours. On the 20th he was still ill, t his pulse had fallen from 140 to 108 and its volume was better. s temperature had risen from 95° to 98° F. and the amount of ne excreted had increased. In addition to getting whole blood was having intravenous saline and dextrose most of the time. swab taken on the 22nd was sterile and the patient continued to prove, his chest being clear and free from pulmonary oedema. e next day he developed a mild phlebitis of the left leg. The p was discontinued.

During the following week he received two pints of fresh blood d polyvalent A.G.G.S. The penicillin drip was continued. On the h his haemoglobin content was 59%. All this time there was a oious serous discharge from the wounds, and precautions were en to give plenty of fluids by mouth or intravenously. The serum otein was investigated, and showed total protein 5.40%—albumin 2%, globulin 2.28% (by difference). An area of redness and elling developed on the inner side of the right thigh, so on July 30 re multiple incisions were made, but only blood and serum ded. This process was repeated a few days later. The swelling the thigh and leg gradually subsided. On the 31st his haemo- bin had fallen to 52%, so more fresh blood was given, and it e to 58% by the next day. A swab showed scanty *Staph. aureus,* erococci, coliforms, and Gram-positive bacilli. A swab taken ee days later revealed Gram-positive cocci, scanty Gram-positive cilli—probably anthracoids—and some resistant staphylococci and erococci.

By Aug. 6 his haemoglobin was 65% and he continued to improve. e serous discharge from the wounds diminished—in fact, most the wounds were now healed; but there was a discharge of pus ntaining bubbles of gas from a few of the wounds above and below original shell wound and the thigh was distinctly resonant on rcussion in these situations. It was decided to operate again, and Aug. 25 the wounds were opened up and from each site, above d below the original wound, a large grey-black spongy slough s removed. The pathological report on these specimens was: The material consists of two masses of soft friable tissue 5 × 2.5 × m. and 9 × 5 × 1.5 cm. The material is necrotic, and muscle is t recognized. Microscopically this is completely necrotic. Adipose sue is the only recognizable one in the section." The patient proved rapidly after this; the wounds (operation and shell) healed mpletely and he was allowed up. He was discharged to his home Sept. 28. All the movements of the limb were complete, but re was, of course, wasting of the muscles and he walked with a p. His general condition was good.

During the course of his illness more than three dozen incisions re made in the thigh, back, abdomen, and chest. He had been en nine pints (900,000 units) of penicillin solution intramuscularly d about 150,000 units of anti-gas-gangrene serum as well as a ond full course of sulphonamides. In addition he had large antities of blood, plasma, saline, and dextrose intravenously.

I acknowledge my indebtedness to the resident medical officer of Royal Victoria Infirmary, Dr. J. H. Craig, who was responsible the intravenous therapy and whose interest in the case contri- ted largely to the happy ending.

The latest report of Dr. H. P. Newsholme as medical officer of alth for the City of Birmingham shows that the year 1943 gave ise for satisfaction in a number of aspects of the public health. w records were reached in an unusually large number of direc- ns. The year saw the lowest infant death rate ever recorded in city; and, with this, the lowest illegitimate infant mortality, ing actually below the particularly low general infant mortality. e city recorded its lowest neonatal death rate for infants under month of age, and its lowest stillbirth rate. The year showed o the lowest notification rate of non-pulmonary tuberculosis so recorded in Birmingham; last, but not least, the lowest maternal ath rate ever recorded in the city was reached in 1943. Against ese pleasant facts Dr. Newsholme notes that, largely as a result of widespread epidemic of influenza, the death rate did not drop ite to the low level of 1942; that there was a 35% increase in number of new cases of syphilis coming up for clinic treatment; d that there was some increase, though not a large one, in new ses of tuberculosis of the lungs in 1943. No substantial change curred during the year in the housing position, and the problem overcrowding as well as that of families housed in dilapidated operty remains very serious.

TWO CASES OF TETANUS

BY

LESLIE COLE, M.D., F.R.C.P.

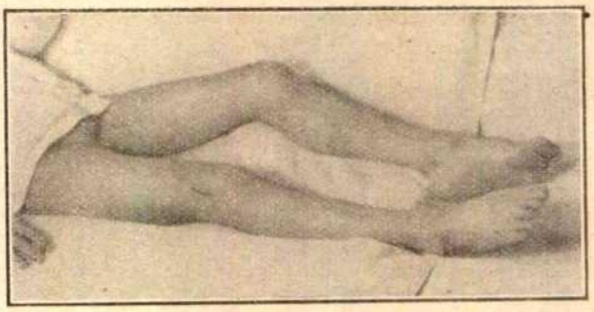
Honorary Physician, Addenbrooke's Hospital, Cambridge

The first of these cases of tetanus is described because it is an interesting example of severe local tetanus developing during the course of a mild generalized attack; and the second —a straightforward example of severe tetanus—because it illustrates certain special points in treatment.

Case I

On Aug. 8, 1944, the patient, a boy aged 5½, trod on a rusty nail, injuring the left foot. No special treatment was given, and the wound appeared to heal satisfactorily. On the evening of Aug. 11 he seemed generally out of sorts and complained of abdominal pain, which woke him up every hour throughout the night. In the morning he had difficulty in opening his mouth. He was admitted to Addenbrooke's Hospital on Aug. 12, about 16 hours after the onset, and then showed the characteristic signs of tetanus: trismus, risus sardonicus, stiffness, opisthotonos, and abdominal rigidity. The foot and leg on the injured side were slightly stiffer than on the other. On the ball of the left big toe was an almost healed wound with no sign of sepsis. There were no other wounds.

Treatment and Prognosis.—200,000 units of antitoxin were given at once, mainly by the intravenous route, and during the next few days trismus and rigidity of the trunk increased. On the 13th reflex excitability increased, and on the 14th he had some slight generalized spasms. Synchronously with the development of these general signs, the rigidity of the left leg became steadily more severe, and by the 14th the whole leg, in contrast to the other limbs, was in continuous muscular spasm and so stiff and rigid that to produce even slight movement at the knee- and ankle-joints required the exercise of considerable force. The leg was slightly flexed at the knee, with the foot plantar-flexed and inverted (see Fig.). Very slight reflex spasms occurred several times daily until the 17th, and tonic rigidity of the trunk and trismus until the 31st. A severe degree of stiffness of the left leg remained throughout the whole illness, and the left foot was still rather stiff on Sept. 9, when the patient was able to walk about. All stiffness, both local and general, had passed off when he was discharged on Sept. 25.



CASE I.—Local tetanus, left leg and foot.

At no stage of the illness were the spasms severe, and 10 gr. of potassium bromide four-hourly and 1½ dr. of paraldehyde per rectum once nightly for the first five days were sufficient to promote sleep.

Case II

On Sept. 17 a boy aged 8 fell off his bicycle, grazing the dorsum of his right foot. This was treated with dettol and bound up, but the wound was not kept very clean. On the evening before admission he felt generally out of sorts and complained of severe backache and difficulty in opening his mouth. These symptoms became rapidly more severe, and he was admitted to hospital on Sept. 27. On admission risus sardonicus and trismus were pronounced, and he could only separate the teeth a quarter of an inch. There was also severe rigidity of the whole trunk with slight opisthotonos. There were a partly healed septic abrasion on the right external malleolus and other scabs on the right heel.

Treatment and Prognosis.—On admission 100,000 units of antitoxin were given intravenously, and the wound was subsequently cleaned and scabs were removed. The signs increased rapidly in severity, and 24 hours after the onset reflex excitability was becoming extremely marked, and, 36 hours after, generalized convulsions were occurring regularly every half-hour, with very severe trismus. Other ominous signs were a rising pulse rate and temperature and inability to take food because of the severity of the trismus. There was also considerable difficulty with micturition.

Both rectal paraldehyde and avertin in basal anaesthetic doses were first tried to control the spasms, but were unsatisfactory because they were not retained. Pentothal, in doses of 0.25 g. intravenously, was then used as a temporary expedient, but was not very successful. Intramuscular paraldehyde in doses of 3 c.cm. was now tried, and as it proved extremely effective it was continued as required for the control of spasms until Oct. 6. For the first few days a dose of 2 or 3 c.cm. was given twice every 24 hours, and later once. To combat the increasing dehydration, an intravenous drip was started on Sept. 28 and was continued for 48 hours, the needle being kept in the vein by a plaster-of-Paris splint to the forearm.

On Sept. 29 the temperature rose to 103°, the pulse to 160, and the respirations to 45. The chest was very bubbly, cyanosis was present, and it was clear that pneumonia would be likely to supervene. Sulphathiazole was therefore given, first by drip and afterwards by mouth, until Oct. 5, to a total of 26 g. The child's condition, which was critical, showed slight improvement on Oct. 2, reflex convulsions became easier to control, and he was able to take fluids by the mouth. His condition then gradually improved, reflex spasms having ceased by Oct. 8 and the tonic rigidity by Oct. 25. He was discharged well on Oct. 30.

Comment

Local tetanus occurs in mild cases most commonly after prophylactic antitoxin has been given. Usually the local signs occur in the injured limb before any generalized symptoms appear. In head wounds, paralysis or spasm of cranial nerves, particularly the 7th and sometimes the 3rd, 6th, and 9th, is another manifestation of local tetanus. It is an important warning that generalized tetanus will almost certainly develop and an indication for giving antitoxin with the utmost dispatch without waiting for trismus or other generalized signs to appear. The work of Abel *et al.* (1938) suggests that local tetanus is caused by toxin absorbed from the wound affecting the motor nerve endings locally before toxin carried round in the blood stream has had time to produce its effect on the motor nerves generally or to involve the synapses in the brain and spinal cord.

In Case I the signs of local tetanus in the wounded limb were very slight when the signs of generalized tetanus were marked, and it was only after antitoxin had been given that the local tetanus developed to an intense degree, persisting throughout the whole illness and even longer than the signs of tetanus in other parts of the body. It is perhaps worth noting that local tetanus of the type described in this case probably occurs without any detectable signs or symptoms of generalized tetanus later. The following is an example of such a case.

An agricultural labourer aged 55 attended the out-patient department complaining of stiffness and rigidity of the left arm from fingers to shoulder. There was very little pain. Over his hand and forearm were numerous small scabs, which appeared to be some weeks old. The condition had come on gradually over a period of about a fortnight and passed off in the same time. There is a strong probability that this was an example of local tetanus in which the absorption of toxin from very slight wounds had been too small in amount to produce any generalized symptoms. The diagnosis in this case could not be confirmed because the scabs had dried up by the time the patient was seen.

Case II is an example of severe tetanus with a period of onset of not more than 36 hours. The whole march of the disease in its early stages suggested a very bad prognosis. The case is described to illustrate the use of three measures which proved particularly helpful in treatment—namely, (1) intramuscular paraldehyde to control reflex convulsions and promote sleep; (2) a plaster-of-Paris bandage to keep the needle of the intravenous drip in the vein during the period when convulsions were frequent and severe; (3) the early administration of sulphathiazole when the possibility of lung infection was threatening. For the first two suggestions I am indebted to my house-physician, Dr. E. Counsell.

TIBIAL BONE-MARROW TRANSFUSIONS IN INFANTS

BY

F. W. GUNZ, M.D., M.R.C.P.
Assistant Clinical Pathologist, Addenbrooke's Hospital, Cambri

AND

R. F. A. DEAN, M.R.C.S., L.R.C.P.
House-physician, Addenbrooke's Hospital

This paper records our experience with transfusions into marrow cavity of the tibia in small children, using the appara described by Janet Gimson (1944). We have employed t method of administering fluids as an alternative to intraven therapy during the past 9 months, and are now setting details of 35 consecutive transfusions. The total number patients was smaller, as more than one transfusion was given the same child in several instances. Nearly all the patie were suffering from dehydration due to gastro-enteritis.

Notes on Technique

In this series we have used the technique described Gimson, and it will be sufficient merely to enumerate so points in which we have deviated from her technique.

The legs are most satisfactorily held by firmly bandag the soles of the feet to a padded splint so that they are ab 9 in. apart, the ends of the splint being tied to the sides the cot. This allows some movement of the legs but preve the needle from being dislodged, and nursing is made eas because the splint is well away from the napkin area. F surgical precautions—mask, sterile gown, and gloves—are tak against sepsis, and the skin is cleaned several times w spirit, then covered with sterile gauze until the needle inserted. The choice of needle is not always easy, beca of the difficulty of judging the thickness of the subcutane tissues and of the tibia itself. The most common mist is to use too large, not too small a needle.

The site chosen is on the flat subcutaneous surface of tibia, at least 1 in. below the level of the tibial tuberos Repeated post-mortem examination showed that even in smallest infants there is a wide marrow cavity extend almost half-way down the tibial shaft, and it is reasonable avoid the epiphysial region by a wide margin. No lo anaesthetic is used for the insertion of the transfusion need The trauma inflicted by the needle seems to be very little m than that occasioned by an injection of novocain, and the p is purely momentary.

The adapter connecting the needle to the giving set is entirely satisfactory. It would seem to need redesigning, as its present form the junction with the needle is easily loose and will sometimes leak in an annoying way. We have us several adapters which we made from cork and rubber tubi and have found them quite satisfactory. A heat-cradle is use in at least two ways: it keeps the bedclothes from touchi the needle and its tubing, and can be used to warm up leg if the drip runs slowly.

The Transfusion

Saline, glucose-saline, Hartmann's solution, and half-streng serum have been given with good results. The rate of fl is usually fast enough to meet the child's total fluid nee but we have used transfusions more often merely to supp ment fluid taken by mouth. The amounts given are sho in the accompanying Table. It was soon found that the d usually needed slowing to prevent the development of lo oedema. The unrestricted rate of flow bears a fairly dir relation to the weight of the child and to the degree dehydration, the fluid running faster with the heavier ch and the greater dehydration, and slowing down automatica as body fluids become replenished. This is in contrast intravenous transfusion, in which the rate tends to be predictable. The cause for this difference seems to be th whereas in intravenous transfusions the rate of flow is det mined by the height of the hydrostatic pressure and the s of the lumen of the vein, the ease of absorption of transfused fluid through capillary walls plays an important part in determining the speed of a bone-marrow transfusion.

If the needle becomes blocked it can be freed by sucking through it a very small amount of fluid with a 2-ml. syringe.

Summary of Cases

Case No.	Age	Length of Needle (in.)	Time of Running (hours)	Quantity Given (fl. oz.)	Reason for Abandoning Drip	Remarks
1	5/12	3/8	5	15	Death	Child moribund on admission. Drip delivered 10 fl. oz. in 2 hours though slowed
2	6/12	3/8	30	40	,,	Drip started at 30 drops per minute and speeded up
3	8/52	3/8	4	15	Oedema	Needle too big for child
4	8/52	1/4	9		,,	Needle loose after 9 hours; ? reason
5	9/52	1/4	26	30	,,	Oedema after 24 hours. Drip stopped. Oedema subsided in 6 hours; returned 2 hours after restarting
6	5/12	1/4	10	47	,,	Very small baby for age. Drip probably too rapid
7	5/12	1/4	12	60	Needle blocked	Completely satisfactory
8	5/12	1/4	24	16	,,	Ran very slowly all the time and was inclined to stop
9	2/12	3/8	24	30	,,	—
10	5/12	1/4	60	50	Death	Needle cleared 4 times
11	6/12	1/2	36	40	Improvement	—
12	6/12	1/2	60	50	Needle blocked	—
13	6/52	1/4	60	60	Death	—
14	8/52	1/4	—	—	Drip unsuccessful from start. Needle probably not in medullary cavity	
15	8/52	1/4	62	70	Oedema	Case of pyloric stenosis. Child taken to and from operating theatre with drip *in situ*. Developed osteomyelitis of tibia
16	9/52	1/4	36	35	,,	—
17	4/52	1/4	16	20	Needle blocked	Case of pyloric stenosis. Taken to and from operating theatre with drip *in situ*
18	3/52	1/4	72	60	Oedema	Very satisfactory
19	4/52	1/4	72	60	—	,, ,,
20	5/52	1/4	48	40	Oedema	Slight oedema after 12 hours. Drip stopped for 4 hours, then continued satisfactorily
21	5/52	1/4	36	20	,,	Ran slowly all the time
22	8/12	3/8	36	40	Death	Necropsy showed localized infection of needle track but not of bone
23	6/12	3/8	22	18	Oedema	Very restless child. Needle loose after 22 hours
24	6/12	3/8	48	40	,,	—
25	6/12	3/8	18	10	Persistent leaking at adapter	Same baby as Case 23; left leg used for both drips. Second drip started 42 hours after discontinuation of first
26	8/52	1/4	72	40	Oedema	Ran slowly throughout
27	7/52	3/8	—	—	—	Very small baby. Needle too long. Drip did not run
28	7/52	1/4	108	80	Stopped deliberately	Same baby as Case 27
29	2/12	3/8	72	Not recorded	Slowness of drip	Fat child. Needle apparently not at right angles to bone
30	2/12	3/8	72	,,	Oedema	—
31	3/52	1/4	132	,,	Death	—
32	3/12	1/4	30	50	Oedema	Drip given too fast; 15 fl. oz. in first 3 hours. Early oedema caused by rapid rate
33	5/52	1/4	48	50	,,	—
34	9/12	1/4	60	40	,,	Ran slowly throughout
35	8/52	1/4	40	40	Death	Ran well

This may cause less damage than the opposite manœuvre—syringing through into the marrow cavity. Oedema is occasionally troublesome, and seems not to depend only on the tightness of the needle in the bone. It sometimes occurs much higher up the leg than the site of insertion of the needle, the region just above the knee being commonly affected. As previously mentioned, leaking at the junction of needle and adapter is another trouble, and even tight and carefully planned strapping does not eliminate it. Leaking due to the needle working loose occurs less often in the early stages, but is a common reason for discontinuing the transfusion after several days.

There is no doubt that osteomyelitis is to be feared. In the one case in our series of saline transfusions in which it developed the operator had not used gloves. Whether or not this led to the infection cannot be decided, but it is considered likely. In no other case was any harmful effect noted, and the relief of dehydration by the intramedullary route appeared to be fully as effective as by any other method.

Use of Blood

The first time this technique was used 2 fl. oz. of whole blood was run in 8 hours into the tibia of a child 2 weeks old who had acute anaemia. The drip then stopped of its own accord and no attempt was made to restart it. No ill effects followed the transfusion. Two other patients were given blood: one was a child 18 months old who had empyema, the other an infant of 11 days with erythroblastosis foetalis. The first received only 4 fl. oz. of blood in 12 hours, although the pressure was raised by suspending the bottle 7 ft. above the leg (Gimson, 1944; Behr, 1944); the second received a negligible amount. In both cases repeated attempts were made to accelerate the rate of flow; both patients developed osteomyelitis, and surgery was needed.

No further attempts at giving blood by this route were made. It is worthy of note that dilution of the blood did not facilitate transfusion. The use of Officer's mixing chamber (Bailey, 1944) was attempted without success.

Comment

There is no doubt that in practised hands the intramedullary drip is valuable in the treatment of small children needing fluids. It is very quickly set up: the insertion of the needle takes only a few seconds, as compared with the 10 minutes or so needed for tying a needle into the internal saphenous vein. But a certain degree of skill is required, and this is borne out by the fact that nearly all the unsatisfactory transfusions in this series were set up—under our supervision—by house officers who had had little experience of the method.

Nursing needs particular care because of the tendency of the drip to run too fast and to speed up after an initial slowness, and because of the ease with which local oedema can develop. We have not been impressed with the regularity of flow mentioned by Gimson. Restarting immediately after the oedema has subsided is not usually satisfactory. The leg may, however, be used for an intravenous drip provided that no oedema is present. The double method was employed several times very effectively.

If precautions against sepsis are adequate there seems to be little risk of infection. A very small hole is left when the needle is withdrawn, and this heals quickly and completely. Two transfusions were given into the same tibia with an interval of 42 hours, which is considered to be the minimum.

Summary

Details of our experience with intramedullary tibial transfusions are given, with a commentary. The conclusion is reached that the method is a valuable alternative to intravenous therapy, but that it is not suitable for the giving of blood.

We desire to thank the honorary staff of Addenbrooke's Hospital for allowing access to their patients.

New Zealand vital statistics are often quoted, and for obvious reasons. The report for 1943–4 of the Director-General of Health, Dr. M. H. Watt, records that the death rate in the Dominion in 1943 was 10.04 per 1,000 mean population. The infant mortality was 31.37 per 1,000 live births, and the stillbirth rate was 26.25 per 1,000 live births. The maternal mortality, including death from septic abortion, was 2.21 per 1,000 live births; when deaths from septic abortion were deducted the maternal death rate was 1.71. Notifications of scarlet fever rose steeply from 457 in the previous year to 1,196 in 1943—the highest number since 1931. The relative immunity of the Maori to scarlet fever is shown by the fact that in 1943 only one case of this disease was reported in the Maori population. The outbreak of influenza in the Northern Hemisphere was watched with some anxiety, but did not reach the shores of New Zealand. In order to minimize the risk of importation of mosquitoes not present in the Dominion a Mosquito Control Committee was set up to collect specimens and carry out surveys in Wellington and Auckland and in the neighbourhood of aerodromes and elsewhere, and on its advice steps have been taken to eliminate all potential breeding-grounds for mosquitoes in and about the ports and aerodromes.

Medical Memoranda

A Clinical Sign of Vagotonia

One of the most difficult decisions a physician has to make is in the small hours of the morning at the bedside of an elderly patient who is in or who has just recovered from an attack of orthopnoea. There is little clinical evidence of disease to help; indeed, extensive clinical examination is too distressing to be employed, and one must be content with a rapid and superficial search for abnormality. Frequently in such a case the chest is emphysematous, there are no accessory breath sounds, and expiration is prolonged and the heart sounds are distant. Temporarily the heart muscle is indicted, and the case is labelled one of cardiac dyspnoea, with all its attendant fears, until a more detailed examination is possible.

Some 10 years ago I noticed in many of these cases the following physical sign, which I have found most helpful in making an immediate diagnosis. When present it is, I claim, an unmistakable sign of vagotonia, producing the symptoms of a paroxysm of bronchial asthma in its initial, waxing, or waning stages. It is often the only indicator of the true cause of the breathlessness complained of by middle-aged or elderly patients. Listening close to the patient's mouth, one hears, without the use of the stethoscope, a fine effervescing bubbling sound during expiration, and in marked cases to some extent in early inspiration. The sound resembles that heard at the neck of a full bottle of soda-water from which the cork has recently been withdrawn. So similar are the two sounds that I have come to call it "the soda-water sign" when speaking of it to others. It cannot be heard through the stethoscope, but its audibility can be increased by folding the morning newspaper for use as a megaphone by the patient or as an ear-trumpet by the physician.

The sign can be banished by the subcutaneous injection of an adrenaline salt, and with it will go the dyspnoea. Further, those cases which have not already developed frank bronchial asthma will do so to a greater or less extent before long: it may be a slight bronchial catarrh with dyspnoea, it may be only dyspnoea on exertion, or it may be a characteristic attack. I have seen it so in many cases, but two stand out in my memory. In the first the sign preceded the asthma by two years, and in the second by five years.

The sign is clearly due to the contraction of the bronchial muscles gradually allowing the inspired air to escape through tubes the lumen of which is narrowed by the spasm and by turgescent mucous membrane covered by a liquid exudate. The rales thus formed are at this stage too delicate to transmit vibrations through the chest wall, but they are conducted up the trachea and amplified by it and the buccal cavity. The recognition of the sign clinically will quickly bring a full realization of its value.

CYRIL J. MURPHY, M.D., F.R.C.P.I.,
Physician to the Meath Hospital, Dublin.

Penicillin in Ophthalmic Therapeutics

The following investigation was carried out in conjunction with Major S. T. Cowan, R.A.M.C., officer in charge of a military laboratory. Its object was to find out what, if any, was the effect on the activity of penicillin of the drugs most commonly employed in clinical ophthalmology.

The drugs tested were: (1) atropine, (2) eserine, (3) adrenaline, (4) cocaine hydrochloride, (5) decicain (amethocaine hydrochloride), (6) argyrol (argent. prot. mite), (7) fluorescein. With the exception of adrenaline, which was used as liq. adrenalin. hydrochlor. 1/1000, the drugs were employed and tested in double the customary strength, so that when diluted with penicillin solution the resultant strength was as desired. Our endeavour was to stimulate as nearly as possible the conditions maintaining in the conjunctival sac.

Procedure.—Penicillin (2 units per ml.) and the drug under test were mixed in equal volumes, and were kept at 37° C. for three hours. The controls were: (1) penicillin (2 units per ml.) + water; (2) each drug + water. After incubation the mixtures were pipetted into porcelain cylinders on plates sown with the Oxford staphylococcus H. The plates were incubated overnight, and the diameter of the zone of inhibition was measured.

Findings.—Argyrol + water diffused into the agar and inhibited the growth of the test organism almost as much as did argyrol + penicillin. Of the other drugs tested none had any inhibitory action on the staphylococcus; only one—adrenaline—inactivated the penicillin in the mixtures.

Additional experiments were made with two solutions of adrenaline hydrochloride. Equal volumes were mixed with penicillin (10 units per ml.) to give a final concentration of 5 units per ml. in the mixture. After incubation at 37° C for one hour the activity of the penicillin was determined as before. With one solution, said to be several years old, the penicillin in the mixture was reduced to about 0.5 unit per ml. With a more recent sample of adrenaline the penicillin was *completed* inactivated.

A. J. CAMERON, M.B., F.R.C.S.,
Major, R.A.M.C.; Specialist Ophthalmologist

Susceptibility to Acute Nephritis

The following case history may be of some interest as illustrating a familial susceptibility to acute nephritis.

Three girls of the same family, aged 10, 7, and 6 years, were admitted to hospital on Oct. 9, 1944. On attending a child welfare clinic three weeks before admission all three children were found to be infested with *Pediculus capitis*. A nit comb was supplied to the mother, and a week later the children's faces became puffy and swollen. This was more marked in the morning on waking up. It was not until a week later when they attended the child welfare clinic again that their heads were seen to be covered with crusts. Castor-oil and zinc ointment was applied to their heads, and bread poultices to their faces. Three days later the children lost their appetites and their urine was noticed to be red in colour. Of the two younger children, one developed oedema of the legs and back and the other of the legs alone. There was no history of scarlatina or sore throat. The mother gave a history of having had nephritis at the age of 18, and a sister of the father had died of "kidney trouble."

On admission all three showed a considerable degree of impetigo, involving the scalp and limbs. There were still many nits present. The two younger children showed oedema of the face, legs, and back. The blood pressure in all three was raised, being 172/120, 152/115, and 160/110. The urine in all three was smoky, loaded with albumin, and contained many epithelial cells, pus cells, and red cells, with a few hyalogranular casts. There was no oliguria, and during their stay in hospital the oedema and blood pressure subsided, and the impetigo rapidly cleared up with dressings of gentian violet. Examination of swabs taken from one of the impetiginous lesions showed *Staphylococcus albus* and a non-haemolytic streptococcus.

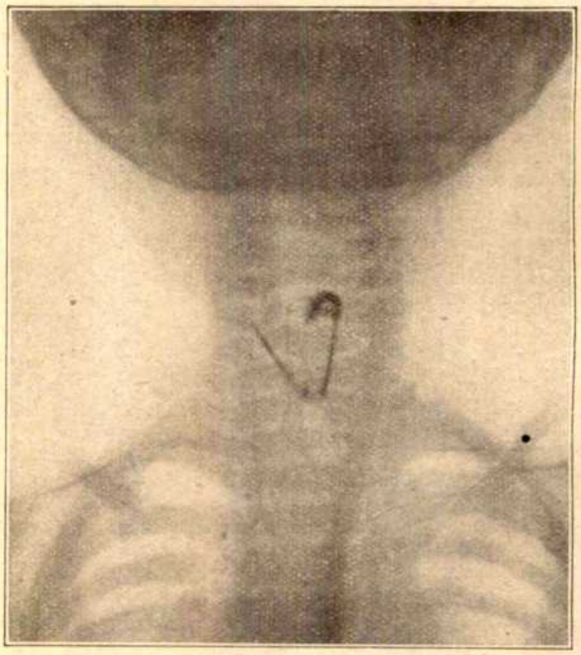
House-physician, Walsall General Hospital.

Open Safety-pin in an Infant's Gullet

I beg to report a case of impacted open safety-pin in the gullet of an infant aged 7 months, and enclose an *x*-ray negative showing the pin *in situ*. [The illustration is reproduced from part of a print.] On account of the tender age of the patient and consequent smallness of the throat, the smallest endoscope had to be used in such a way that its beak kept the soft tissues away from the sharp point. The forceps devised by the late Dr. D. R. Paterson were passed down the throat outside the lumen of the endoscope in order to grasp the sharp point. General anaesthesia was necessary. The infant was able to leave hospital (Southern General, Glasgow) apparently unscathed after a few days' observation to rule out hidden trauma.



Glasgow. D. RITCHIE PATERSON, F.R.C.S.ED., D.L.O.

A Case of Adder Bite

Dr. Batt's communication in the *Journal* for Aug. 5, 1944 (p. 181), prompts us to report a case of adder bite which recently came under our care. About 8 p.m. on the evening of June 29 one of us (E. R. W.) was called urgently to see a rather delicate little girl aged 11 years at a farm about seven miles out in the hills. On arrival it was found that the child, while picking wild strawberries in a railway cutting, had been bitten on the tip of the right forefinger by an adder about an hour previously. She had managed to make her way home, about half a mile uphill. She was very collapsed, was of greyish-white appearance, and vomited incessantly. On the tip of the finger was an indolent-looking wound like a 3- to 4-day-old laceration from barbed-wire injury, surrounded by a blackened area. She made no complaint of pain then or subsequently. A thin rubber band was applied to the base of the affected finger; the wound was incised, but could not be induced to bleed more than a drop or two, and some gelatinous-looking material—presumably the snake toxin—was wiped out. Potassium permanganate was placed in the wound and an injection of nikethamide (coramine) was given. The finger was dressed with a saturated magnesium sulphate solution.

In spite of her shocked condition it was decided to transfer the child to Pembroke County War Memorial Hospital, Haverfordwest, 12 miles away. She was very collapsed during the journey by car, and nikethamide was given. She was admitted to the hospital: notes of her progress are reported below.

It is of interest to record the attempts made to obtain antivenene serum. The station commander of a near-by airfield was telephoned and gave the prompt assurance that he would arrange for any supply of serum to be flown to the hospital without delay. The hunt for antivenene then started. A call was first put through to the London Zoo authorities, who replied that their instructions were to refer all such inquiries to the Ministry of Health. The Ministry was contacted, and they replied that although they held no stock of serum they would communicate with the Zoo. It was explained that the Zoo had already been approached. The Ministry then undertook that if any serum could be found in London it would be rushed to the specified airfield in the morning. This was midnight.

A little later the R.A.F. station commander rang up to say he had been informed that there might be some serum at the Royal Hamadryad Hospital, Cardiff. The latter hospital was rung up, and referred us to the Royal Infirmary, Cardiff, but they had none. The R.A.F. commander again rang up in the small hours of the morning to say he had communicated with a large American hospital in the Midlands and had been referred by them to a vaccine-manufacturing firm in the West Country. Negative results were again obtained. The Ministry of Health, however, was as good as its word, and about midday on the 30th ampoules of antivenene prepared by the Pasteur Institute, Algiers, arrived at the hospital by plane from London.

CASE HISTORY

A girl aged 11 was admitted to the Pembroke County War Memorial Hospital at 9 p.m. on June 29, 1944, with a history of being bitten by an adder on the pulp of the index finger of the right hand.

On admission the patient's general condition was poor. She was very shocked and cyanosed. The pulse was imperceptible and she vomited copiously a bile-stained fluid. A black discoloured wound was present in the pulp of the index finger. She was treated for shock. Half an ampoule of nikethamide was given 2-hourly for three doses and rectal salines 4-hourly. There was no swelling of hand or arm on admission. At 12 midnight the back of the right hand started to swell, vomiting ceased, and pulse quality and rate improved.

On the morning of June 30 the right hand was very swollen and slightly discoloured. There was no swelling of the arm. At 9.30 a.m. the finger tourniquet was removed and this was immediately followed by much swelling and lymphangitis of the whole arm, extending to the axilla. Hypertonic saline compresses were applied 2-hourly, with saturated magnesium sulphate compresses to the wound. Rectal salines were continued, with fluid freely by mouth. At 2.30 p.m. 5 c.cm. of serum was given intramuscularly. This was repeated at 5.30 p.m., and there was immediate improvement, general and local.

July 1: General condition improved. Hand and arm still swollen, with marked lymphangitis of arm and much greenish-yellow discoloration on the inside of arm. Large purple bullae around nail of affected finger. Nail snipped, with liberation of much dark-brown serous fluid. July 2: Swelling decreasing; lymphangitis subsiding; discoloration of arm still marked. July 3: Slight further improvement; finger-tip and nail very discoloured. July 4: Improvement; discoloration of finger and arm continues. July 6: Yellowish discoloration of forearm very marked; fair amount of purulent discharge from finger. July 7: Urticarial rash appeared, of a generalized distribution. Improvement continued, and patient was discharged on July 26.

COMMENTARY

In our belief the condition of the child was critical and dangerous for 24 hours immediately after the bite. The local and general condition improved markedly after injection of antivenene. Points to be noted are: the great difficulty of obtaining serum and the apparent lack of available supplies; and the not infrequent occurrence of adder bite: several cases have come to the care of one of us (E. R. W.). We suggest that antivenene should be available to practitioners of every rural county, through the M.O.H. or local hospital.

Haverfordwest. A. B. DAVIES, F.R.C.S.Ed.

Gold Nephritis and Dermatitis in Pulmonary Tuberculosis

Gold is used mainly in the treatment of rheumatoid arthritis and pulmonary tuberculosis. Toxic reactions are not very common, but among them skin rashes are greatly feared owing to the long time they take to clear up. Nephritis with oedema is a rare complication which usually takes some time to resolve. Douthwaite (1944) recently said that he has seen one case which recovered after three months. The following case is of interest as the woman developed nephritis and dermatitis at the same time, both of which had cleared completely in five weeks.

CASE HISTORY

Mrs. X., aged 26, has bilateral pulmonary tuberculosis. General condition good. Weight steady; temperature range 98–99°; pulse 82–96. Physical examination showed diminished respiratory movement in the right upper zone, with increased tactile fremitus, dullness on percussion, bronchial breathing, and fine rales anteriorly. Posteriorly there were fine rales in the right suprascapular region and on the left side at the medial end of the scapular spine. Radiographs showed: (R.) Medium shading in upper zone with a cavity 1 in. in diameter; (L.) a small area of fine shading in the first interspace. The patient's sputum contained acid-fast bacilli on direct smear; and the E.S.R. (Westergren) was 26. She was kept on bed rest, but the temperature did not settle and serial radiographs showed progression of both lesions. It was therefore decided to induce a right artificial pneumothorax; and also to give gold therapy because of the involvement of the left side. Myocrisin intramuscularly was started on May 9, 1944, and given weekly. The dosage was 0.01, 0.02, 0.05, 0.1, and 0.15 g.—a total of 0.33 g. having been given before toxic symptoms arose. The urine was tested for albumin on the day of administration and on the day after. An R.A.P. was successfully induced on May 22, and adhesions requiring section were later found.

Seven weeks after the start of the gold course, and six days after the last injection, a rash appeared. This was a generalized red maculopapular rash, most marked on the legs. The submandibular and inguinal glands were enlarged, and the urine contained no albumin. On the third day the rash was confluent and pruritus marked; stomatitis was present and there was puffiness of the eyelids and face. The temperature had also started to rise, reaching its maximum on the ninth day of illness with an evening reading of 101.4° F.

On the fourth day there were generalized pitting oedema and oliguria. Weight was increased 6 lb.; B.P. 130/80. The urine contained a trace of albumin. The diet was restricted to one pint of glucose orangeade a day, and an intake and output chart was kept. Lotio calaminae was prescribed for the pruritus. Fifth day:—Peeling of face, chest, and limbs started; urine clear and remained so afterwards. Seventh day:—Weight up 9 lb. Eleventh day:—Oedema was still present, with a daily average output of 18 oz. The face was now covered with a weeping eczema, and the rest of the body had the appearance of a typical exfoliative dermatitis. Lotio calaminae oleosa *B.P.C.* was applied to the face, and the rest of the body was covered with a paste made of

℞	Pulv. zinci ..	dr. 2
	Pulv. amyli ..	dr. 2
	Paraffin. molle ..	oz. 1
	Ol. ric.	q.s.

Fifteenth day:—Dermatitis on legs started to improve. Vasomotor paralysis present in legs—blanched on raising and becoming purple on hanging down. Sixteenth day:—Temperature started dropping by lysis. Diuresis began with an output of 41 oz.

On the twenty-eighth day only the face was affected with a scaly eczema. Paste was applied. The weight returned to normal and the diet was increased; the temperature was normal. By the thirty-fifth day the face had cleared.

This patient therefore had a gold nephritis, which cleared in three weeks, and simultaneously a dermatitis, of which there was no sign whatsoever after five weeks.

I wish to thank Dr. Dennison Pickering, medical superintendent, Pendyffryn Hall Sanatorium, for permission to publish these notes.

R. GRENVILLE MATHERS, M.B., Ph.D.,
Physician, Pendyffryn Hall Sanatorium.

Reviews

STUDY OF CANCER IN ARGENTINA

Memoria del Instituto de Medicina Experimental para el Estudio y Tratamiento del Cancer, 1940-43. By Prof. A. H. Roffo. Buenos Aires. 1943.

There could be no stronger evidence of the noteworthy contribution of Latin America to the progress of medicine than this comprehensive report of the Institute for the Study and Treatment of Cancer. The Institute began its work at Buenos Aires in 1922 on a small scale, and has increased steadily in size and influence until it is now one of the largest and best-equipped institutions of its kind in the world. Since its commencement 120,000 patients have come under supervision, representing more than a million and a half consultations and treatments. Within the scope of the Institute are included not only the care and treatment of patients at dispensaries for early diagnosis, out-patient clinics, and hospitals, but also the training of nurses, the spreading of information to the general public and to the medical profession, and the experimental investigation on a large scale of all aspects of the cancer problem.

The report now issued, a large volume of 700 pages, includes a mass of statistical data in tabular form. Taken alone such tables are apt to prove dull reading, and they have therefore been supplemented by anatomical and other diagrams which show at a glance the incidence of the various forms of cancer and the results of treatment. Much has been achieved by early diagnosis, and it is a striking comment on the value of the work to note that in 1924 81% of the patients did not apply for treatment until the disease had been present for six months or more, whereas in 1943 70% came under observation during the first three months of illness, and 48% in the first month. Naturally enough, cancers of the skin, the larynx, and the breast were seen at an earlier date than, for example, cancer of the uterus, which is so apt to escape recognition.

Eight thousand persons attended the dispensaries for early diagnosis and treatment in 1943. In the provision of hospital accommodation it has been found that cancer patients can be more effectively treated in small rooms containing only a few beds than in a large ward, in which the surroundings are apt to be disturbing to a mental outlook already greatly upset. In the new pavilions of the Institute each room accommodates only one or two patients. Statistics show that town and country each contributes an equal number of patients, and that there is a similar equality between the two sexes, and also between Argentines and foreigners. A series of maps illustrate the locations in the Republic from which the patients are derived.

A study of the site of cancer in a large series of cases reveals some interesting facts. The skin is the tissue most frequently involved, and this frequency appears to be increasing—from 10% of total cases in 1926 to 24% in 1943. The great majority of skin-cancers affect the neighbourhood of the face, especially the lips and nose. Another region in which cancer is met with in mounting frequency is the lungs. There were 98 cases in 1942—3% of the total. The increase of motor traffic and of the use of oil as fuel may partly account for this rise in incidence. Next in frequency to skin cancer are cancers of the uterus (15%) and the breast (12%). Tongue, oesophagus, and stomach each contributed 4%, rectum and larynx 3% each.

Another section of the report deals with the information derived from histological investigations. There were 7,000 biopsies in four years. Carcinomas (5,000) far outnumbered other forms of tumour, which included 1,500 benign tumours and 200 sarcomata. The remarkable effect of deep *x*-ray therapy upon some of those cases of sarcoma is illustrated by a series of photographs; and the equally striking results of what is termed "proximoroentgenterapia" in skin cancer are also illustrated. A full account is given of the *x*-ray and radium treatment of uterine cancer, including the technique and dosage. Modern apparatus is described, and there is a brief account of the physical basis of radiotherapy. Next comes a description of deep *x*-ray therapy and of its effect upon normal and diseased tissues. While this remains the method of choice in the majority of cases, many cancers of the ski were treated by radium and radon. Surgical treatment wa adopted in only 10% of the total cases, the organs mos frequently involved being the stomach, the breast, and th larynx. The diathermy knife or needle was the instrumen preferred. The efficiency of the "follow-up" method whic has been adopted is shown by the completeness of the statistica information which concerns the results of treatment.

One of the most interesting sections of the report consist of a series of 97 abstracts of papers on various aspects of th cancer problem which had already been published in th Bulletin of the Institute. To those pages—502 to 553—man experts may turn with profit. No less important is th synopsis of lectures and demonstrations given during the perio under review, not only to students and practitioners but als to nurses, for whom special training in "cancerologia" i provided. The volume concludes with copies of the clear an concise directions which are issued to patients, to visitors and to nurses, and with an account of the antitobacco campaig which the Institute has promoted among Argentine students.

The report is richly illustrated with excellent photograph of the Institute and its equipment. It is a publication whic reflects great credit upon Dr. Angel H. Roffo, Professor o Cancerology and Director of the Institute.

DOUGLAS GUTHRIE.

GENERAL MEDICINE IN 1944

The 1944 Year Book of General Medicine. Edited by George F. Dick, M.D., J. Burns Amberson, M.D., George R. Minot, M.D., William B. Castle, M.D., William D. Stroud, M.D., and George Eusterman, M.D. Pp. 768; illustrated. 18s. 6d.) Chicago: Year Book Publishers; London: H. K. Lewis and Co.

The Year Book of General Medicine for 1944 continues it useful systematic record of steady progress, though there i nothing startlingly novel to report. It is noteworthy that eve in America there are signs of a revolt against excessiv dependence on laboratory tests. There is an interesting revie by Moscheowitz of what he terms the hyperkinetic group o diseases, characterized by exaggerations of normal bodily functions with morbid structural changes as a s quel. Example are: (i) hypertension of the greater circulation, which represent an exaggeration of normal arterial pressure, leading to arteriosclerosis and its consequences; (ii) Graves's disease, in whic there is an exaggeration of the normal basal metabolic rate (iii) peptic ulcer, in which one of the dominant features i exaggerated gastric secretion of acid; (iv) cardiospasm, spasti colon, and other instances of an exaggeration of normal tonicit and peristalsis; (v) manic-depressive psychosis, representing a exaggeration of a normal rhythm; (vi) paranoia, an exaggeration of the affective functions. These maladies have a commo denominator in a maladjustment between the psyche and th environment, and are mostly products of civilization.

Choosing almost at random from the articles which hav interested us, we would mention the study of infective hepatiti (p. 35) and the proof that complete structural recovery of th liver cells can occur (p. 675); also the evidence that in anterio poliomyelitis (p. 67) and in pernicious anaemia the nervou lesions are by no means confined to the spinal cord. It ha often been supposed that conditions characterized by marke asthenia might be due to a functional inadequacy of the adrena cortex; this is substantiated by the discovery (p. 740) that suc individuals are unable to conserve their chlorides, just as ar sufferers from Addison's disease.

HEALTH PROBLEMS FOR EVERYMAN

Battle for Health. A Primer of Social Medicine. By Stephen Taylor, M.D., M.R.C.P. (Pp. 128. 5s.) London: Nicholson and Watson.

Since Dr. Stephen Taylor wrote his brilliant description o "the suburban neurosis" he has been well known as a vigorou exponent of the social aspects of medicine. His latest contribution, *Battle for Health*, forms one of a rather militan series—*The New Democracy*. In it he points the path for th wayfaring man, aided by vivid isotype diagrams which ma be a help to the comprehension of some people. The boo is well illustrated, though surely the picture of a graveyar is unnecessary. Interesting portraits of medical pioneers ar added, though in one instance there must be a mistake: unde Sir Charles Sherrington's portrait the date of his birth is give as 1875, which would mean that he took his Tripos at the age of 6. But such things do not interfere with the general merit of the book, which attains its purpose of informing the ordinary reader of the main facts in the history of the fight against disease, and the factors involved in the maintenance of health. Nor will the medical man fail to find interesting information therein. Knowledge is, in the author's opinion, a necessary key to health for everyone, for "this is not a job for doctors alone. It is a job for all of us. . . . Health is not to be found in the medicine cupboard nor yet in the pages of 'keep fit' magazines; both breed rather hypochondriasis." Rather must we look to scientific analysis of the problem and a logical synthesis of the results. Dr. Taylor is careful to point out that there are aspects of the problem outside the ambit of the doctor: housing, compulsory pasteurizing of milk, no more ribbon development or suburban sprawl, for instance. To pretend that a national health service by itself can remedy such causes of ill-health is a fraud on the public. One cannot but admire the sincerity and generous sympathy of the author.

Notes on Books

The publishers and editors of the *Year Book of the Eye, Ear, Nose and Throat* have continued faithfully to discharge their annual task with obviously no slackening of standards or diminished zeal. A peculiar mixing of the paper is explained as a device to maintain the same bulk with papers which have to conform to certain wartime standards of production. This, however, has been arranged so that the quality of the illustrations is maintained. There has perhaps been a general scarcity of the best class of medical literature in recent years owing to preoccupation with military work, diversion of effort into other spheres, and general lack of leisure for research and literary work. There can, however, be found much worth attention in all the sections of the book, even if some of it seems to be rather repetitive, and the specialists concerned still lie under a deep obligation to the accuracy and discrimination of the editorial control. The 1944 edition is published in this country by H. K. Lewis and Co. at 18s. 6d.

A Textbook of Physiology, by Profs. William D. Zoethout and W. W. Tuttle, is now in its eighth edition (London: Henry Kimpton; 25s.). As we said when noticing an earlier edition, this American work is meant to fill the gap between the larger textbooks and books of an elementary character, and should be useful to students working for the Conjoint or for examinations in pharmacy, domestic science, etc. The first chapter, dealing with protoplasm and its environment, has been almost entirely rewritten, and in other respects there is evidence of careful revision. Much of the advanced chemistry and the more detailed anatomy are now set in smaller type so that the student may pass them over without losing his main thread.

A fifth edition has now appeared of *Notes on Clinical Laboratory Methods*, sponsored by a standing committee set up by the Faculty of Medicine of the University of Glasgow to secure uniformity in the laboratory technique employed in clinical teaching at Glasgow. The field covered is equivalent to side-room testing as usually carried out by students of medicine, with some further tests which they may conduct in the clinical laboratory. The booklet is published by John Smith and Son (Glasgow) Ltd., Gibson Street, Hillhead, Glasgow, at 3s. 6d. There are blank pages at the end for the student's own notes.

The Discovery of the Uses of Colouring Agents in Biological Micro-Technique, by John R. Baker, D.Sc., is now published as a monograph of the Quekett Microscopical Club, at whose 743rd meeting in London on July 13, 1943, the author read it. Dr. Baker hopes that his essay may be of interest not only to historians of science but also to biologists and biochemists in general, and we think it will. It is concerned with the use of colouring agents in microscopical studies and does not deal with macroscopical reactions except incidentally. The publishers are Williams and Norgate, Ltd., 36, Great Russell Street, W.C.1, and the price is 1s. 6d.

Dr. Raphael E. G. Armattoe, now of Londonderry, has written a short account of *The Swiss Contribution to Western Civilization*, published at 5s. (post free 5s. 2d.) by W. Tempest: Dundalgan Press, Dundalk. Dr. Julian Huxley commends the pamphlet in a brief foreword, and recalls that Swiss freedom has been prolific of benefits to the world at large. "It is also encouraging to reflect that Switzerland is the one real centre of science, learning, and culture in Europe which has been able to remain out of the war." D . Armattoe disclaims any pretension to have given a comprehensive survey of Swiss men of science and letters. His criterion for listing men in his work is that they made a definite contribution to knowledge or left the world a happier, a better, or a more beautiful place than they found it.

Lieut.-Col. F. A. Barker, I.M.S.(ret.), has written a valuable report, *The Modern Prison System of India*, in which he outlines the progress of prison reform in that country during the twenty years following the publication of the report of the 1919–20 Indian Jails Committee. The author has taken a prominent part in Indian penal administration for nearly 30 years and is thus well qualified to appraise the work so far accomplished. The volume is published at 10s. 6d. by Macmillan and Co., under the auspices of the Department of Criminal Science of the Faculty of Law in the University of Cambridge. Lord Hailey contributes a foreword; and Prof. P. H. Winfield, in a preface, remarks that Col. Barker's book not only clearly describes the prison system in India but also gives a vivid account of the many factors that make the problems connected with the system infinitely more complicated than those with which we have to grapple here.

Preparations and Appliances

APPLIANCE FOR A NEW METHOD OF MASSAGE

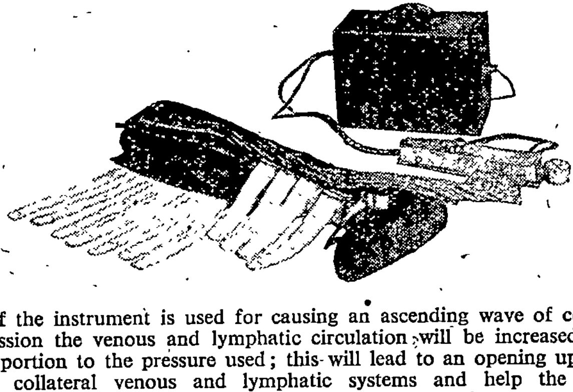
Dr. W. T. Hunt (Acton, W.3) writes:

By means of an instrument consisting of a series of cuffs, similar to that in a sphygmomanometer, which are repeatedly inflated in rotation to any desired pressure and then simultaneously deflated by means of a motor pump, operating through a controlling mechanism, waves of constriction can be sent up a limb, hastening the return flow in the lymphatics and veins or causing a passive congestion if directed distally.

The cuffs are incorporated into sheaths made for the upper or lower limbs, which can be quickly applied, and the pressure in the cuffs readily controlled by turning one knob; there is a pressure gauge contained in the apparatus, and the motor works from an ordinary lamp socket or wall plug. The instrument is easily transportable in two small hand cases.

Ascending compression is employed with this instrument in the following conditions: Milroy's disease (hereditary oedema of the legs), lymphoedema, callous oedema after fracture or injury or phlebitis, and oedema due to varicose veins, erythrocyanosis, "white leg," cardiac and renal conditions, intermittent claudication, and in treating unsightly oedema from an unknown cause in women. This treatment can also be employed to free a limb of oedema before Kondoleon's operation is performed, being used as near as possible up to the time of operation and afterwards to establish connexions between the skin flaps and underlying muscles.

Descending compression can be employed to tide over an arterial crisis—e.g., embolism—to break up a clot, or to restore circulation, and also for Buerger's and Raynaud's diseases, chilblains, frost-bite, and crush syndrome.



If the instrument is used for causing an ascending wave of compression the venous and lymphatic circulation will be increased in proportion to the pressure used; this will lead to an opening up of the collateral venous and lymphatic systems and help the recanalization of blocked veins. If used in the opposite manner the arterial circulation will be increased, causing an intermittent passive congestion. If there is a wound, ulcer, or other painful area on a limb the instrument can be so adjusted that compression is exerted up to and away from the area so that no pain is experienced by the patient.

It has been found that the best results are achieved if the instrument is applied for one hour twice a day; if less time is given the course of treatment must be of longer duration. The patients can apply and control the instrument themselves, so that in suitable cases a stay in hospital or nursing home is not necessary.

This instrument, under the name of "pneumassage," is manufactured by Messrs. Allen and Hanburys Ltd., Wigmore Street, W.1.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 17 1945

TREATMENT OF BURNS

In 1942 the Medical Research Council initiated a scheme of research into the treatment of burns and scalds and invited Dr. Leonard Colebrook to organize suitable arrangements at the Royal Infirmary, Glasgow. The impressive volume of studies now issued[1] gives evidence of the success of the venture and encourages the hope that the plan will be extended in the peaceful days to come. Two themes stand out from the many inquiries set in motion by the Glasgow team. The first is that infection must be prevented or reduced if burns are to be healed expeditiously and with minimal disability and death from sepsis eliminated; the second emphasizes the tremendous value of plasma transfusion, so-called "replacement therapy," in the early critical period when fluid is draining away from the circulation, thereby adding serious embarrassment to a patient whose vital reserves are impaired.

The main object of first-aid treatment of burns should be the prevention of streptococcal infection. Haemolytic streptococci are widely distributed in all communities, being recruited from septic sores, sore throats, and "running ears," as well as dispersed in the nasopharynx of many healthy carriers, variously estimated as 5 to 30% of the population. They lurk, too, in the noses of "nasal carriers," whence they continually seep on to handkerchiefs, clothes, hands, finding their way into the air and dust of public places and private houses, where they remain viable for long periods in dust, bedding, and the like. A fresh burn, like any other kind of injury, is thus liable to early contamination unless strict precautions against infection are taken at once. The injured skin should be protected with a recently laundered clean towel or a sterile cloth, and the patient removed to hospital if the burn is severe, where an elaborate attack on what is essentially a major surgical problem can be attempted. If the burn is quite superficial, or in the case of more severe burns when considerable delay in getting into hospital is anticipated, the Glasgow "No. 9" cream should be freely smeared on the affected region. Here, again, contact with infected sources such as blankets is to be avoided, and interference with blisters is not advised. The operator's hands should be thoroughly washed and dried and a gauze mask or clean handkerchief worn over the mouth and nose. The cream—whose chief constituents, cetyl trimethyl ammonium bromide and sulphanilamide, have been the subjects of intensive bacteriological studies by the Glasgow team—should not be left on the burn for more than two days, since there is a slight risk of dermatitis arising if it is left longer.

With the more severe cases a serious strain is placed upon the judgment of the surgeon, for he has to decide whether his treatment shall be directed towards "cleaning up" of the burn or resuscitatory measures against the circulatory collapse which threatens. Experience shows more and more that the prime necessity is the treatment of "shock" rather than infection at this stage, and there may be time only for some slight extension of the correct first-aid measures. When the patient's condition has been restored to a state in which thorough attention to the burn can be given, then an elaborate ritual is instituted. This calls for the elimination of every possible source of infection, whether it be the dust-carrying air of operating rooms and wards, the blanket and bedding and dressings, or possibility of cross-infection from personnel concerned in the treatment. The full discussion of the innumerable sidelines of this complicated business makes fascinating reading in the Glasgow team's report. No aspect of hospital life escapes attention. The difficulties in supply of nurses under the rigours of wartime, troubles over sterilization of blankets and gowns, influence of black-out restrictions and blast walls on ventilation and fumigation, vagaries of the seasons and their disturbance of insect population—all these afford a record of obstacles encountered and overcome against a background of life in a busy institution. And success of encouraging proportions has been achieved, for acute septic infection became rare and fatalities few. Nevertheless, the members of the team feel that further improvement can be achieved in controlling or preventing certain types of infection, especially those arising in the later stages of the sloughing period of deep burns and due to coliform and diphtheroid bacilli, *Proteus*, staphylococci, and at times *Ps. pyocyanea*. The acquisition of infection during the stay in hospital is still a matter for concern, especially in the case of haemolytic streptococci, while there is room for improvement in methods of preventing local fluid loss from burns. Bactericidal agents, too, demand more study. Suggestions for further progress include the institution of centres specially staffed and equipped for the treatment of burns, where there will be close collaboration at all times between the surgical and nursing staff and the investigator; where, in other words, the burns problem will be thought of with due regard to its sociological, therapeutical, and investigational implications. The high incidence of disability from burning is not confined to wartime conditions only, but is a problem of considerable national importance at all times and deserves serious consideration in schemes for improving the nation's health.

The second theme of the Glasgow team's report is the value of replacement therapy in the treatment of burn shock. Fluid loss from a burnt area may go on for 24 to 30 hours, leading to serious haemoconcentration and, if untreated, precipitating a circulatory crisis which too often proves fatal. Since the primary consideration in these grim cases must be the preservation of life, it is very important that guiding principles be laid down for variable conditions of injury. These the Glasgow workers have been able to formulate. With fluid replacement, for instance, there is no short way out through calculation by means of formulae. Careful study of each individual is necessary, preferably using serial determinations of the haemoglobin value and the blood pressure. Adults with burns of over 15% of the body surface, and children with burns of over 5 to 10%, require generous transfusions which will make good the fluid loss and prevent haemoconcentration. Complete cleansing and dressing of the burns should be postponed, even until the second or third day, while the problem of fluid wastage exists. No time must be lost in instituting adequate replacement therapy; even a short delay may be followed by the most serious outcome. The absence of striking changes in the blood picture and blood pressure is no reason for complacency, and the surgeon must concentrate on maintaining a circulatory blood volume as nearly unchanged as possible in order to safeguard against "shock" and its complications. Even when the initial difficulties are safely overcome there remain a number of problems, many of which are still being investigated. Anaemia often enough develops, nitrogen equilibrium is disturbed, while plasma protein loss has to be made good through the regenerative powers of the individual. Progress in these complex matters can be made only by the co-operation of highly trained members of a team. The Medical Research Council workers have shown what can be done in this way, but a great deal still remains to be tackled.

NUTRITION AT HOME AND ABROAD

It is now more than two years since the *Times* advocated the formation of a Nutrition Council in a leading article which stressed the importance both of keeping in touch with nutritional trends at home during the war and of providing machinery for the rapid assessment of malnutrition in reoccupied Europe in order to obtain the most rapid and efficient administration of food relief.[1] Letters to the *Times* and leading articles in this *Journal*[2] continued the debate; and, although they differed about the best way to set up a Nutrition Council, they agreed that such a body should be formed. A year ago an analysis of the situation, based on a report to the Parliamentary and Scientific Committee, was made by Dr. John Yudkin,[3] who pointed out that a comprehensive food policy must include, first food production, secondly food distribution, and thirdly nutritional surveys, with a view to determining whether the object of production and distribution—adequate nutrition—was being achieved.

It is opportune now to look at the more immediate problems of wartime nutritional trends at home and to the relief of malnutrition in Europe. A quick glance shows that the picture is confused. The Ministry of Food has made its own surveys and has a fairly clear idea of what ordinary working-class families are eating. Comprehensive investigations have been made by the Oxford Nutritional Survey. But none of this work has been published, and so we are left with the impression that systematic, repeated nutritional surveys at home have been few. Davidson and his colleagues[4] have reported on a large number of haemoglobin estimations, which indicate a fall in the earlier years of the war and a slight rise during the last two years. Yudkin[5] [6] found an increase in the heights and weights of Cambridge school-children between 1942 and 1943 and in the weights of factory workers between 1941 and 1943. There have been other *ad hoc* clinical investigations. But certainly there is not enough published evidence to justify the statement often made that the nutrition of this or that group, or of the country as a whole, is satisfactory.

On the basis of a report by Magee[7] the *Times*[8] concluded that "the nutritional condition of the population is well maintained and may even be improving." The report is based on three nutritional surveys, carried out in 1942 by Sydenstricker, in 1943 by Hawes and Stannus, and in 1944 by Adcock and Fitzgerald. According to their figures the proportions of subjects who were of "good" nutrition were 77% in 1942, 82% in 1943, and 94% in 1944. But are these valid data for demonstrating a supposed improvement in nutritional state between 1942 and 1944? First, the methods of assessment were clinical, and anyone experienced in this type of work will agree that observations from three sets of observers, however well versed in each other's ways, cannot be compared except with the greatest of reservations. Secondly, the places where the surveys were carried out differed appreciably in economic status. The survey of 1942 was made in areas "selected with one exception because of their bad economic history"; the survey of 1943 was in areas many of which had suffered from the depression; and the survey of 1944 included many areas in which the economic situation was good, and few in which it was bad. It therefore does not seem possible to accept the figures—as the *Times* has done—as an index of "well-maintained" or even "improving" nutritional state. The figures quoted by Magee cannot be taken to show anything other than that nutritional state is dependent on economic state—a common enough observation, which was nevertheless well worth repeating.

The question of the relief of Europe is critical, and even if there is a grave lack of transport there does not seem to be a clear-cut plan for the supply of food to liberated areas. Have the military authorities organized the rapid, mobile nutritional teams suggested in the *Times* two years ago? Or are they leaving it to U.N.R.R.A., and, if so, where are *its* teams? The need for emergency relief foods is urgent, and the means to distribute them quickly and widely must be found.

NEW WAYS OF GIVING PENICILLIN

The great drawback to systemic penicillin treatment is the necessity for either continuous or frequent administration. The drug is rapidly absorbed and excreted in the urine, so that intramuscular injection must be repeated regularly every three hours if an adequate level is to be maintained in the blood, unless a continuous drip, either intravenous or intramuscular, can be established. One way of overcoming this difficulty would be to secure delayed absorption from the site of injection, so that less frequent doses would be necessary. Two methods of doing this have been devised, and both have been applied so far, not to relieving the seriously ill patient from his dreaded nocturnal awakenings by the needle but only to reducing the number of injections required for curing gonorrhoea from the usual five or six to only one. M. J. Romansky and G. E. Rittman[1] [2] have made a suspension of calcium penicillin powder in a mixture of beeswax and peanut oil; a single intramuscular injection of 100,000 units or less of this preparation will maintain an adequate blood level for 7 hours or more, and cured 11 out of 12 cases of gonorrhoea. An alternative method used for the same purpose by M. Trumper and A. M. Hutton[3] was to strap an ice-bag to the arm for 2 hours before and up to 12 hours after injecting a watery solution of penicillin into the deltoid. Chilling caused diminished circulation and hence slow absorption. A single dose of 50,000 units maintained an adequate blood level in most cases for as long as the ice-bag was kept in position, and sufficed for the cure of 17 cases of gonorrhoea, the only failure being in a man who received a smaller dose.

An alternative method of maintaining the blood level is to obstruct renal excretion. The capacity for retaining penicillin is probably the only advantage to be gained from having nephritis. Patients with damaged kidneys in whom a high blood level persisted for 8 hours or more after their last dose have been reported by several writers, but the two patients described by J. H. Humphrey[4] are so far unique. A single dose kept their blood bacteriostatic for nearly five days. This was the consequence of an extreme oliguria, and since the urine passed had the composition of almost pure glomerular filtrate, and contained no detectable penicillin, it is suggested that the drug is normally eliminated by the tubules. This excretory mechanism has previously been surmised on the ground that the excretion of other substances by the tubules will delay that of penicillin. Diodrast was shown to have this action by C. H. Rammelkamp and S. E. Bradley,[5] and it is now reported by K. H. Beyer *et al.*[6] that the same effect can be obtained with para-aminohippuric acid. In the experiments described this substance was given by continuous intravenous infusion. If no simpler method of administration will serve, this proceeding is unlikely to become popular in clinical practice.

With supplies of penicillin rapidly increasing, the time may come when less attention need be given to economy and a greater consideration will be the patient's comfort. This happy prospect has led A. H. Free *et al.*[7] to reconsider the possibility of giving penicillin by the mouth. This route has hitherto been firmly ignored because the drug is destroyed by acid, and even administration by duodenal tube has resulted in poor absorption. With a much larger dose the result might be different, and these authors therefore caused four normal subjects to swallow a single dose of 100,000 units. Blood titrations were not done, but the amount excreted in the urine was determined, and varied from 8,800 to 33,600 units: presumably gastric secretory activity was the main factor in this variation, and it would be interesting to be able to compare these figures with the results of test meals. The sufferer from achlorhydria should be at a great advantage when penicillin is given by this route, and diminished gastric secretion is said to be a common accompaniment of severe febrile illness. Oddly enough, when sodium bicarbonate was given at the same time the output of penicillin was much less. Renal excretion, though greatest in the first hour, was substantial up to the fourth hour; action may therefore be more prolonged than that after intramuscular injection. It need scarcely be said that this wasteful method of administration is quite unjustified at the present stage, but it may repay further exploration in the coming age of plenty.

NON-MAGNETIC INTRAOCULAR FOREIGN BODIES

Intraocular foreign bodies present a series of related problems: the injury induced by the entry of the foreign body, the liability to infection, and the irritant action of the foreign body. The matter is rendered still more complex by the danger of sympathetic ophthalmia arising from any perforating wound of the eye. The one relieving feature in this picture is the success that has attended magnet extraction of foreign bodies since the procedure was first introduced by Dixon in 1859. In peacetime industrial accidents are responsible for most of the eye injuries with retained foreign body, and two out of three such foreign bodies are magnetic. The proportion of non-magnetic to magnetic foreign bodies was much higher in the injuries seen in the last war than in industrial accidents, and this unfavourable disproportion has become still more accentuated during the present war. This has come about because of the increasing use of aluminium in the manufacture of projectiles, and except for shell and bomb fragments most missiles may now be regarded as non-magnetic. The position thus created was the subject of a Hunterian Lecture by Mr. L. H. Savin two years ago, who brought the subject up to date in a paper at the Royal Society of Medicine last week. In his Service patients with retained intraocular foreign body the proportion of magnetic to non-magnetic foreign bodies was one in six, and it was still more unfavourable in air-raid casualties, who showed a proportion of one in nine. The use of the sulphonamides is an innovation that materially helps to combat the attendant infections, but the gravity of the problem of these retained foreign bodies is made more real by our ignorance of the reaction of the eye to aluminium. Leber had shown that intraocular foreign bodies could be classified chemically as inert, weakly active, and violently active. Chemically stable foreign bodies were not acted upon by blood or tissues, and might remain in the eye for years without causing inflammation. In contrast to gold and glass, which were thus inert, iron and steel gradually became oxidized, were taken up by the ocular tissues, and induced degenerative changes, while mercury—and to some extent copper—led to suppuration.

In a series of carefully planned experiments on the rabbit Savin studied the reaction of the eye to aluminium. Fragments of pure aluminium and various alloys were implanted into the anterior chamber, vitreous, or on to the retina, and in every case changes took place in the fragments. Pure aluminium may be absorbed completely, but more often the fragment becomes coated with a white deposit of aluminium hydroxide, or with fibrin and gelatinous material. In many cases the metal crumbled and pieces became scattered. Lens and vitreous changes were late results in almost all cases, and there was evidence of retinal damage. These experimental results were supported to some extent by clinical observations in a patient he had under observation. It is thus clear that aluminium is not inert, and its removal from the eye presents a formidable surgical problem. Accurate location of these non-

magnetic foreign bodies is essential, as a successful forceps extraction is more likely in the anterior segment of the eye than in the posterior segment. Stressing that in the vitreous and retina the odds are against the surgeon, Savin dvises, pending improvement in technique, that the surgeon should attempt removal only in those cases in hich clinical observations show the foreign body to be deleterious. This is sound but depressing advice.

THE PSYCHIATRIST AND THE PSYCHOLOGIST

sychiatry has made big strides during the war and is now being applied to other than strictly medical problems. For instance, psychiatrists are now employed by the Army to advise upon the likelihood of a given cadet becoming useful officer. This tendency is to be welcomed. Such work provides an excellent education for the psychiatrist; nd temperamental factors, on which the psychiatrist is entitled to speak with some authority, have a clear bearing on the problems of personal selection. The psychiatrist as thus begun to tread on the territory of occupational sychology, and the common field of activity has become Tom Tiddler's ground disputed by both.[1-4] It is clearly desirable to find a compromise satisfactory to psychiatrists nd psychologists alike. Though the psychiatrist and the psychologist are at times concerned with the same problems, they approach them from different standpoints and with types of experience that are complementary. Clearly, what is required is the closest and most friendly collaboration. When a psychiatrist says that because of certain temperamental qualities a healthy man is unsuited to become an officer he is working by a rule-of-thumb method which has not been fully proved. He does not know how many men who have proved themselves satisfactory officers in the hard school of experience have been possessed of these same temperamental qualities. On the other hand, actual neurotic symptoms, which may be concealed until enquired into, are the peculiar province of the doctor and are known to be incapacitating. Where the psychiatrist approaches the problem from the point of view of the morbid the psychologist approaches it from the point of view of normal variation. His training has proceeded along very different lines. In order to solve the problem of which men are most suitable for certain jobs, and what jobs are most suitable for certain men, he has been taught to examine the requirements of the job, to devise tests or these requirements, and to try out these tests on an adequate scale before putting them extensively into operation. His training has provided him with knowledge of a number of different classes of occupation, and with a familiarity with an armoury of scientific and statistical techniques which are and must remain beyond the reach of any but a few medical men. To the bystander it would seem that both types of experience are needed for a solution of the problem, and that while the psychiatrist should claim final judgment about the handling of the man who through neurosis or other cause has fallen below his usual level of efficiency, he should admit the greater appropriateness of the psychological techniques of vocational guidance and personal selection for the placing of men who are medically healthy and well. The problem of placement may, however, in the individual case have an unmistakably therapeutic aspect, and where this is so the doctor should be consulted. Although the psychologist may have suggestions to offer on the subject of treatment—e.g., in the neuroses or in disorders of behaviour—the final decision must lie in the hands of the doctor. In recent years, particularly in the field of child psychiatry, psychologists have sometimes embarked on the treatment of individual patients without adequate medical supervision. It is to be hoped that the unsuitability of this arrangement will be recognized by psychologists themselves.

INTRATHORACIC NERVE TUMOURS

Tumours originating from nervous tissue are not uncommonly found in the chest; they are usually termed benign new growths, but their pathology receives little attention in standard textbooks. Such tumours are often symptomless, or very nearly so; they are often discovered by accident, when the chest is radiographed for some other reason. Mass miniature radiography will therefore probably reveal quite a number of these growths; in fact, Brooks[1] reported finding 4 intrathoracic neurofibromata in a series of nearly 2,000 healthy men examined by this method, and these amounted to one-third of all the tumours discovered in this group. An authoritative account of intrathoracic nerve tumours by Kent, Blades, Valle, and Evarts Graham[2] is therefore particularly welcome. These authors attack the prevailing misconception that these tumours are benign. In their small series of 18 examples no fewer than 7 showed definite malignant change. They have also collected 105 cases from the literature, 39 of which were considered to be malignant, and they point out that this proportion of malignancy corresponds to that found among nerve tumours elsewhere in the body.

Neurofibroma is the commonest tumour of the posterior mediastinum and posterior part of the superior mediastinum, and almost invariably favours these sites. The origin of the growth is still doubtful; it probably arises in a nerve sheath, either from the connective tissue or from the cells of the sheath of Schwann. The type most usually encountered in the chest consists of fibrous tissue with some nuclear clumping and palisade formation, as seen in a Schwannoma; this tumour grows from the intercostal nerves. A less common variety, which contains numerous multipolar ganglion cells, is usually termed a ganglioneuroma and may arise from the sympathetic system. Some neurofibromata show both types of structure. It is not uncommon for the tumour to originate within an intervertebral foramen, in which case it often extends into the spinal canal. The symptoms may be very few: pain is not uncommon, and other effects occur as the result of pressure or nerve involvement. *X*-ray examination shows that the tumour is usually single, rounded, homogeneously opaque, and situated in the paravertebral region; pressure may cause erosion of neighbouring ribs. A lobulated appearance may be due to rapid growth and indicate malignancy; but the presence of an effusion does not necessarily mean that the tumour is malignant.

The best treatment for an intrathoracic neurofibroma is surgical removal; usually this is not difficult, though an extension into the spinal canal may occasionally give trouble. These tumours are not sensitive to irradiation, and the proved high incidence of malignant change does not justify the policy of waiting for pressure effects to appear before advising operation. Kent and his co-workers conclude their account of these tumours with an illustrated record of all their cases, which will be most instructive to those interested in the subject.

The Joint Tuberculosis Council and the National Association for the Prevention of Tuberculosis have arranged a refresher course for tuberculosis officers and medical practitioners, to be held in Manchester at the University, Oxford Road, from April 23 to 26. The fee of £4 4s. is payable in advance to Dr. Harley Williams, Tavistock House North, Tavistock Square, London, W.C.1.

A YEAR'S WORK AT A WARTIME NURSERY

BY

J. L. BLONSTEIN, M.R.C.S., L.R.C.P.

The following is an account of a year's work at a wartime day nursery (Battersea Central Mission) established in a much-bombed area in London. The nursery is open to children between the ages of 2 and 5 whose mothers are doing war work. The mothers pay a shilling daily, while the Ministry of Health contributes a shilling a day per child.

The nursery is housed in seven rooms each 20 ft. by 15 ft. on one floor, and there are three rest rooms, one dining-room, one isolation room, one schoolroom, and one playroom. In addition there are two bathrooms and two lavatories. There are two women cleaners who work full time.

The average number of children attending daily (except Sundays and bank holidays) from April 1, 1943, to March 31, 1944, was 50. There were twenty boys and thirty girls. They spent on the average eleven and a half hours (7 a.m. to 6.30 p.m.) daily at the nursery. A matron (State-registered nurse and registered fever nurse) is in charge, and there are one State-registered nurse, one teacher, and four junior nursery assistants. The medical officer attends on one set afternoon weekly. He examines new entrants and re-examines at regular intervals children already admitted. Children are immunized against diphtheria (one injection 1/2 c.cm. A.P.T.) and given prophylactic inoculations of whooping-cough vaccine with the consent of their parents. The medical officer is on call at any time during the day to attend to emergencies, and children who need treatment at home are referred to their own doctors.

Daily Diet

There is one special cook and one help in a kitchen on the premises. The average daily diet is as follows: *Breakfast.*—Bread, butter, cereals, bacon, jam, marmalade, hot milk. *Lunch.*—Meat, two vegetables (in season), potatoes, gravy, steamed pudding, custard, milk puddings, stewed fruit when available, orange juice. *Tea.*—Bread-and-butter, jam, honey, marmite, grated cheese, green salad (in season), home-made cakes, milky tea. Concentrated orange juice and cod-liver or halibut-liver oil are given daily.

Children up to the age of 3 play with toys and enjoy simple singing games such as "Farmer's in his den" (in the open air, weather permitting). They have regular meal- and washing-times, and spend one and a half hours sleeping in centrally heated rooms, well ventilated, from 12.30 to 2 p.m. Children from 3 to 5 years also enjoy toys and games in the open air and attend a nursery school from 9.30 a.m. to 11.30 a.m. During the two hours' instruction the occupation is changed every ten minutes so that their interest does not flag. They enjoy singing, recitation, percussion band, short stories connected with animal life, fairy tales, and Bible stories. They also sing and clap nursery rhymes and enjoy elementary education, including the alphabet and number activities. They also have physical exercises accompanied by the piano, and often enjoy playing with constructive toys such as building bricks, jigsaw puzzles, and posting boxes.

The average number of days lost through sickness was 7. There were the following cases of infectious diseases: Rubella 4, scarlet fever 2, diphtheria 2, chickenpox 6, and measles 1. Among other illnesses were tonsillitis 6, mastoiditis 1, bronchitis 5, abscess of neck 2, pneumonia 1. The fact that there were no cases of whooping-cough speaks highly for the prophylactic vaccine. Schick tests were performed on all children attending the nursery, and despite the fact that they had all been immunized 23 were positive and re-immunized. Out of the 23 positive reactors 21 came in with a history of having been inoculated at "clinics." It seems, therefore, unwise to rely on the mothers' statements; all new entrants should be Schick-tested.

The average gains in height and weight during the year were as follows: *Height.*—2 to 3 years, 1 to 1½ in.; 3 to 5 years, 1½ to 2 in. *Weight.*—2 to 3 years, 5½ to 6 lb.; 3 to 5 years, 6 to 7 lb.

The above notes are given in the hope that they may be some assistance to medical officers in charge of nurseries or those contemplating their organization.

The January–February issue of *Industrial Welfare and Personnel Management,* the journal of the Industrial Welfare Society, includes an article on the employment of the blind in industry by Major E. Wittkower and Patricia Elton Mayo. This reports six weeks' research work at a factory employing a group of blinded persons. The authors point out in conclusion that the blind are only a section of the severely war disabled, and experience gained from employment of the blind points to the need for an association analogous to St. Dunstan's for the after-care of other severely disabled men.

A PLAN FOR BATH

The "Plan for Bath," prepared by Prof. Patrick Abercrombi Mr. John Owens, the City Engineer, and Mr. Anthony Mealan Town Planning Officer, was opened by the Minister of Tow and Country Planning, Mr. W. S. Morrison, on Feb. 1, with th Mayor of Bath, Councillor Edgar Clements, presiding.

The Exhibition fills the whole of the Victoria Art Gallery an consists of general and detailed plans, perspectives of many o the principal proposals, maps showing the open spaces, the agr cultural belt, and the use of land over the area covered by th proposals. Indeed, one merit of the scheme is that it include a wide area around the City of Bath. The planners were tol by the Bath and District Joint Planning Committee—whic under the chairmanship of Sir Arthur Hobhouse, chairman o the Somerset County Council, was responsible for the prc posals—to ignore boundaries. The Exhibition includes dia grams showing the water, drainage, and communications i relation to the surrounding district, and among other things th area served by the Bath Royal United Hospital. There is als an extremely interesting series of plans showing the conditio of the Georgian houses and buildings, and how these would b affected under the new plans. Provision has been made fo the extension of the bathing establishment, a large concei hall, and recreational facilities. In close relation to the bathin establishment is a site for the new Royal National Hospit for Rheumatic Diseases (Mineral Water Hospital) and a Healt Centre comprising facilities for research laboratories and othe medical purposes. There is also provision for a rehabilitatio centre and hostels for industrial workers who do not need t go into hospital. Furthermore, accommodation is provided fo the health department of the city. The Health Centre i almost equal in size to the area of the ancient Roman town o Aquae Sulis.

SUFFERINGS OF OCCUPIED HOLLAND

PROTEST BY DUTCH PHYSICIANS

A strong protest by members of the Dutch medical professio has been made to the German commissary in Holland, Seys Inquart, concerning the conditions in the occupied country The protest is unsigned, but it is said to represent the feeling of thousands of doctors. In the first place the complaint i made that the Dutch Red Cross has been placed under th administration of an individual who does not enjoy the cor fidence of the Dutch people. The institution, says the lette has now become a German instrument, with which Dutch doc tors can no longer co-operate.

The principal charges made in the letter, however, have t do with the conditions under which the people in the occupie Netherlands now have to live. The German administratio is blamed for the increasing shortage of foodstuffs. The ration have a value of 600–800 calories a day, which is less tha one-third of what the working adult requires. Milk for smal children is insufficient, and special feeding for the weak an ill has been stopped entirely. Tuberculosis, dysentery, disease of the alimentary canal, and infantile paralysis are declared t be rapidly increasing, while epidemics of diphtheria and scarle fever have reached proportions hitherto unknown in the Nethe lands. The German administration is cited as responsible fo this state of affairs, first, because, in contravention of inte national law, the Germans took away the reserve stocks whic were available in 1940, and, secondly, because the Dutch peopl are now prevented, owing to confiscation of transport, fro distributing evenly such food as remains. The Germans blam the Dutch railway strike as the reason for the famine condi tions, but it is pointed out that in normal times the railway transported only a small proportion of the supplies.

Still worse are the conditions under which Dutchmen hav been rounded up for labour drives. It is stated that these me have been harried until they have fallen from sheer exhaustio and have been crowded together without the elementary necessi ties of life. One instance is given of a number of civilians i November last who were marched from Rotterdam to Del in pouring rain and then locked up in trucks without strav fifty or sixty men to each truck. They had no sanitary co veniences, and they had no food other than what their loc compatriots could spare from their own meagre rations. Th hygienic conditions in the camps where these labourers are housed are described as appalling. There is hardly any medical care, and it is difficult to get sick persons taken to hospital. It has even been demanded of the doctors that they should provide a healthy man for every sick one taken away.

If, as a number of highly placed German officers declare, this is not a labour drive but a prisoner-of-war camp, it is pointed out that the conventions relating to prisoners of war are flagrantly contravened.

The letter concludes with a declaration which must have caused the medical profession in the Netherlands, with its great traditions, much heart-searching before it was made—namely, that in view of all these happenings it is becoming increasingly difficult for Dutch doctors to maintain the humanitarian attitude of giving the same attention to both friend and foe.

"You will have to realize that if you wish to make use of the services of the Dutch doctors in the future, such aid will only be given because of professional duty, and because they would not like to be considered as being upon the same level as their opponents. On account of this professional duty, however, the Dutch doctors send you this letter, now that the distress of the people requires them to speak their mind."

Reports of Societies

MALARIA IN BRITAIN

At a meeting of the Fever Group of the Society of Medical Officers of Health on Jan. 12, with Dr. M. Mitman in the chair, a discussion on malaria in this country was opened by Mr. P. G. Shute, Malaria Officer to the Ministry of Health.

Malaria, he said, was endemic in England as late as the 19th century and reached epidemic proportions in certain areas. In 1917–18 a number of cases of indigenous malaria arose from infection of the anopheles by soldiers returning from abroad; in 1917 there were 330, but from 1920 onwards there were very few. In England the only species of anopheles likely to be important in malaria transmission was *A. maculipennis,* which was most densely distributed in low-lying marshy districts. He estimated that possibly hundreds of thousands of malaria-infected troops would return to this country at the end of the war, and the spread of malaria to the civil population was a foregone conclusion. But this prospect was less formidable than it appeared. Infection with *Plasmodium ovale* was readily cured, showed no tendency to relapse, and should not trouble us in post-war years. *Plasmodium malariae,* although it survived in man longer than any other species, was not easily transmitted, since gametocytes (sexual parasites) were rare. European strains of parasites causing malignant tertian malaria readily infected English anophelines, but usually died out in the mosquito before the cycle was completed, unless the atmospheric temperature was 75° F. or higher. Also the attack in man was fairly readily cured, and often tended to burn itself out completely within six months. Only one indigenous case of malignant tertian malaria was reported in this country after the last war, and spread to the civilian population appeared equally unlikely after this one.

In benign tertian infection relapses were common and parasites were available to the mosquito in the peripheral blood for some days before clinical relapses occurred. The parasitic cycle could be completed even at low temperature, and heavily infected mosquitoes could remain infective after they had fed as often as on 30 separate occasions. Infected varieties normally living in close association with man could therefore give rise to many cases of malaria. Benign tertian was the form of malaria most likely to arise as an indigenous infection in this country. With high atmospheric temperatures a few cases of malignant tertian might occur from European strains, but returning troops should not be infective to mosquitoes for more than a single summer. Nevertheless, rapid diagnosis and prompt treatment of indigenous cases were of the utmost importance in view of the known virulence of this species, particularly in a non-immune population.

Prophylactic Measures

In benign tertian infections prophylactic mepacrine offered transient protection only. Returning troops so protected might experience their first attack of malaria many months after arriving in this country, and frequent relapses would follow. Latency was a normal feature of benign tertian infections, but where mepacrine prophylaxis was practised it might be seen in the majority. Neither quinine nor mepacrine possessed gametocidal properties, which were important so far as infectivity to the mosquito was concerned. Pamaquin in small doses of 0.02 or 0.03 g. would destroy gametocytes in 24 hours and could be given on the first and second days of relapse. Mepacrine should not be administered at the same time, but quinine could be used. The value of the mosquito net should be borne in mind, especially in districts where *Anopheles maculipennis* was abundant. The destruction of a few mosquitoes in a house where there was a case of malaria would probably do more to prevent the disease spreading than the destruction of hundreds of thousands of mosquito larvae in their breeding-grounds. Antilarval operations as a general precautionary measure did not appear to be justified, especially where breeding-grounds were extensive. Measures against adult insects would prove the most efficient way of reducing their numbers in any locality. The insecticide used should kill instantly and leave no smell. A number of new insecticides were available, including D.D.T., which promised well, but final judgment on its effectiveness against mosquitoes should be reserved.

Mr. Shute pleaded for early diagnosis in indigenous cases and for a blood film in suspected cases before antimalarial drugs were given. One thin and one thick film should be taken; the first spread so that the red cells almost touched without overlapping; a thick film should be spread over an area the size of a sixpence, and just so thick that print could be seen through the drop of blood when the slide was lying flat on it.

Dr. R. McCallum described 48 cases of benign tertian and 1 case of malignant tertian malaria in soldiers returned from the Middle East. All were mild, with typical clinical courses. Twelve of the men had no history of a previous attack while in the malarious area. In the diagnosis of a primary attack relative monocytosis was suggestive. Treatment was on standard lines with quinine, mepacrine, and pamaquin, and could be completed within three weeks in most cases. As the hospital was in an area potentially malarious owing to the presence of *Anopheles maculipennis atroparvus* with suitable breeding-grounds, precautionary measures included the use of mosquito nets, pyrethrum spraying, and the administration of a dose of pamaquin to the patient. No case of indigenous malaria had occurred in the surrounding population.

The Blood Film in Diagnosis

Major J. W. Howie, R.A.M.C., said that some aspects of the laboratory diagnosis of malaria required emphasis. Thin films must really be no more than one cell thick or the stain would not penetrate properly. Thick films were often made too thick; one or two drops of blood were enough, and the blood should be spread gently and evenly so that the hands of a watch could be seen through the dried specimen. He preferred Leishman's stain for thin films and Field's or Giemsa's for thick films. The distilled water must be adjusted to a reaction near neutrality, otherwise malaria pigment and stippling would be missed and differentiation of species would be more difficult. This was important, because relapses in malignant tertian malaria could best be prevented by mepacrine, whereas in benign tertian malaria quinine and pamaquin would give better results.

From each case of suspected malaria a thick and thin film should be made: the thick film was essential when parasites were few, the thin film was needed to determine species. It was sometimes mistakenly supposed that blood films should be taken when the patient's temperature was rising; the chances of detecting parasites were highest if films were made when the temperature was falling, and the absence of pyrexia was by no means a reason for not taking a blood film. Several films should be taken at intervals of 3 to 4 hours; 5 minutes' examination of four films made at these intervals was far more useful than the prolonged scrutiny of a single film. There should be no half-measures about the interpretation. A properly stained film showed unequivocal red and blue staining in the structure of parasites; unless an object in the film showed this, it was not a parasite.

The laboratory worker could help in controlling treatment by estimating the concentration of antimalarial drugs in blood and urine. Some of this work involved complex procedures, but there was one useful and simple test that any laboratory could perform—the Tanret test for quinine in the urine (*Lancet*, 1943, **2**, 317). If this was not positive during quinine administration the disease would not respond: the patient was evading the drug, or his absorption was defective, or his tissues were destroying it with undue rapidity. A persistently positive Tanret test in successive urines would soon be followed by a good clinical response; but if the Tanret test was negative or irregularly positive, quinine or mepacrine must be given parenterally.

It was dangerous to wait too long in serious malignant tertian infections before administering parenteral quinine, which was still the best treatment for cerebral malaria. Quinine should not be given in blackwater fever, but if there was any difficulty in controlling severe malignant tertian infections there must be no delay in giving intravenous or intramuscular quinine. The improvement was usually dramatic, and a patient who had previously vomited the drug could often take and absorb later doses given by the mouth.

A patient whose malaria had rendered him anaemic (red cell count below 2,500,000) would show a reticulocytosis of 10 to 20% over three days or so when his infection was fully controlled. If this reticulocytosis failed to appear in an anaemic patient or a submaximal response—about 4%—was noted, it might be assumed that the infection had not yet been fully controlled.

Dr. C. A. Bentley thought the Romanowsky stain was more stable in tropical conditions with high humidity than Leishman's. The persistence of malaria in a locality depended on the ratio of mosquitoes per head of population. Thus the disease would be most unlikely to spread in big towns but might do so in sparsely populated areas in this country. Dr. E. H. R. Harries said that the precipitating factor in an attack was often a change of environment or conditions, and the possibility of cerebral malaria in troops returning from abroad must be borne in mind.

Correspondence

Penicillin in Bacterial Endocarditis: Investigation

Sir,—The place of penicillin in the treatment of subacute bacterial endocarditis has not yet been established, although encouraging results have been reported in America, and these suggest that prolonged treatment with large doses may be effective in some cases. It is apparent that more information is required on the effective dosage in relation to the sensitivity of the organism to penicillin, and the Penicillin Clinical Trials Committee of the Medical Research Council has therefore established ten centres in which patients will be treated according to a prepared plan, and with full laboratory control. Physicians are invited to refer patients suffering from subacute bacterial endocarditis to any of the following:

London.—(*a*) Sir Alexander Fleming, St. Mary's Hospital, London, W.2. (*b*) Resident Medical Officer, Middlesex Hospital, London, W.1. (*c*) Prof. R. V. Christie, Hill End Hospital (St. Bartholomew's), St. Albans.

Liverpool.—Prof. Henry Cohen, Department of Medicine, the University, Liverpool, 3.

Sheffield.—Prof. E. J. Wayne, Royal Hospital, Sheffield, 1.

Leeds.—Dr. J. R. H. Towers, 42, Park Square, Leeds, 1.

Manchester.—The Resident Medical Officer, Manchester Royal Infirmary, Manchester, 13.

Bristol.—Prof. C. Bruce Perry, Department of Medicine, Canynge Hall, Whatley Road, Bristol, 8.

Edinburgh.—Dr. A. R. Gilchrist, Royal Infirmary, Edinburgh.

Belfast.—The Secretary, Belfast Penicillin Clinical Trials Committee, Queen's University Institute of Pathology, Grosvenor Road, Belfast.

—I am, etc.,

Ronald V. Christie,
Secretary, Penicillin Clinical Trials Committee.

Penicillin

Sir,—I was very much interested in the excellent series of articles that you have published on penicillin in your issue of Jan. 27. Those of us not yet privileged to have a supply other than what we can make for ourselves will have to possess our souls in patience till such supplies are available.

In company with many other people I was greatly surprised at an article in the daily press of a week or two ago quoting a case that had had about 900,000 units of penicillin, and stating that the cost of this was £400. This agrees with the cost alleged to have been incurred in treating another case, so there would seem to be some foundation for the rumour, though it is a little difficult to see how the information can have leaked out, seeing that the stuff is not on the open market as yet. If this is indeed the price that the "penicillin ring" is demanding the firms involved should surely be called upon to justify such an inordinate charge. I have myself taken a hand in making penicillin (though the peculiar state of the law only permitted it to be given away), and am quite sure that there is no valid excuse for the cost to be as much as a tenth of that amount.

I note further that each ampoule is marked with an expiry date. It would be interesting to know what happens to these ampoules in hospitals carrying a large supply. If kept in a refrigerator the worst that happens is surely only a fall in titre, and there must be hundreds of people who would give their eyes for the use of these ampoules, even if their titre is diminished, rather than they should suffer the fate of being merely discarded.

There was one other point of interest in the article by Dr. G. H. Tee (p. 118) on a case of meningococcal meningitis treated with penicillin. He states that penicillin was given with good results, but that a change to sulphamezathine allowed a relapse to occur with temperature up to 104°. This is so strikingly at variance with the remarkable effect of sulphamezathine given *ab initio* that it would seem necessary to consider the possibility that the penicillin may have some influence in spoiling the effect of the sulphamezathine in much the same way that the converse is supposed to occur.—I am, etc.,

Haywards Heath. J. W. Shackle.

The Action of Penicillin

Sir,—With reference to your recent articles and leader on the action of penicillin (Jan. 27, p. 123), it is interesting to recall the work of Louis Pasteur, our greatest benefactor, who, as far back as 1865, established the fact that *Penicillium glaucum* was endowed with chemical properties of a highly selective nature.

All students of chemistry are familiar with the history of the tartrates, and how the laevotartaric acid can be separated from paratartaric acid by the action of the mould, which destroys the dextro-acid. *Penicillium notatum* is now known to have an even more astonishing selective action—that of destroying micro-organisms without damaging tissue cells. Is it possible that penicillin has the power of breaking down some chemical body present in the organism and/or essential to its existence, and which may exist in some of their offspring in an isomeric combination, and thus account for the "persisters"? Possibly those who have studied the chemical action of penicillin could throw some light on the matter and produce evidence to disprove any such theory. In the meantime we are faced with the fact that two members of this family are endowed with selective powers, which should be an additional stimulus to research among the lower forms of vegetation in the hope that we may find a further ally capable of penetrating the hide of the tubercle bacillus.—I am, etc.,

Uley, Glos. J. G. Fayrer Hosken.

Treatment of Trachoma with Penicillin

Sir,—A number of Russian nationals have been treated for trachoma in this hospital. These cases have been seen by Mr. G. W. Black and diagnosis confirmed. Every case showed a well-marked vascularization of the cornea and pannus formation, especially of the upper tarsal conjunctiva.

Case 1.—Admitted with a chronic ulcer of right side of neck, proved later to be tuberculous, secondary to a tuberculous adenitis. Intramuscular penicillin (384,000 units) was given, the secondary infection resolving, and the ulcer at last showing evidence of healing. At the end of the course he was noticed to have a conjunctivitis, diagnosed on examination to be trachoma. Penicillin drops (16,000 units per c.cm.) given 3-hourly. The inflammation subsided rapidly; reduction in pannus noticeable. No evidence of recurrence yet.

Case 2.—Diagnosis of trachoma. Penicillin 16,000 units per c.cm. given; 3-hourly drops in both eyes for 3 days.

Cases 3 and 4.—Both had bilateral trachoma. These cases were given the standard treatment—a 25-g. course of sulphathiazole followed by mercuric oxychloride 1/1000 drops, and copper sulphate 1/1000 4-hourly, treated at the same time as Case 2, and used as controls.

In Case 2 the inflammation of the conjunctiva resolved rapidly, and photophobia diminished quickly; the eye was practically clear in 3 days. In Cases 3 and 4, at the end of the standard treatment (3 days) the conjunctiva was still inflamed and the photophobia undiminished. These cases were given the above course of penicillin and resolved rapidly.

These four specimen cases of trachoma resolved rapidly under penicillin treatment. It still remains to be proved that it has a specific effect on the "virus" causing the disease, or whether the effect is only transitory, clearing up the secondary infection present in all these cases. I am unfortunately unable to follow up these cases to see whether the condition recurs.

My thanks are due to the medical superintendent, Dr. J. N. Hill, for permission to publish these cases, and to Dr. J. Heggie for the supply of penicillin.—I am, etc.,

County Hospital, Otley. G. H. GILFORD.

Immediate Repair of the Cervix

SIR,—I agree with Mr. Mortimer Reddington's plea for attention to the cervix after delivery (Jan. 13, p. 60) and his reference to the unfortunate results if such care is not given, but would like to make the following observations based on a considerable number of post-natal examinations carried out about six weeks after delivery.

1. Satisfactory results are obtained by application of coagulation diathermy to superficially damaged cervices at about the sixth week post partum or even later.

2. Deep tearing of the cervix rarely occurs when relaxation and dilatation are encouraged by the use of chloral hydrate or possibly pethidine, with avoidance of mechanical dilatation or attempted delivery by forceps before full dilatation, or by Caesarean section in certain selected cases.

3. Difficulty is experienced in obtaining a satisfactory and permanent result by primary cervical suture, even under good conditions in hospital. I have twice found the external os almost completely occluded by sutures.

For the arrest of haemorrhage immediate suture may be necessary, but I submit that the majority of patients whose cervices are torn may be saved from any of the future complications enumerated by Mr. Reddington by coagulation diathermy or, in a very few instances, by trachelorrhaphy at a later date. In spite of the fact that immediate repair of the cervix is advised in many standard works on obstetrics, there seems to be a wide discrepancy between theory and practice, for, on inquiry, I find that such a step is rarely deemed necessary in some of the largest maternity hospitals, and for similar reasons to those I have given.—I am, etc.,

Liverpool. S. B. HERD.

Episiotomy and Perineal Repair

SIR,—It is gratifying to see so much correspondence in the *Journal* these days on the important subjects of episiotomy and perineal repair. Dealing with the perineum, Mr. Mortimer Reddington summed up the matter well when he wrote recently, "In a few well-applied and knowledgeable stitches you may secure the whole of a woman's happiness" (*Clin. J.*, 1944).

I heartily endorse Mr. Reddington's letter (Jan. 13, p. 60) on the subject of immediate repair of the torn cervix. In my experience, however, perineal and cervical repair can be carried out just as efficiently in a country cottage as in a hospital, provided one has taken the trouble to draw up a well-prepared plan in advance to deal with the condition. Mr. F. Neon Reynolds's letter (Jan. 27, p. 128) is excellent and contains many points worthy of close attention. I, too, am opposed to midwives doing episiotomy, and agree that Dr. Flew's indications are rather wide.

The idea that the stretched perineum is anaesthetic to any appreciable degree is pure myth. Few other subjects abound with such myths as does obstetrics. In few other subjects is the truth more obvious. To perform episiotomy, or to repair a torn perineum, without adequate anaesthesia is in all circumstances inexcusable. In a hospital pentothal is admirable for episiotomy. Local analgesia, however, is excellent when kindly used, and is undoubtedly the ideal for perineal repair. Nupercaine 1 in 1,000 in normal saline, with adrenaline 0.001%, and without the addition of irritating preservatives, is the best solution to use. Both in quality of anaesthesia and freedom from tissue irritation this local anaesthetic surpasses all others.

Regarding the technique of perineal repair, may I stress one or two points?

(1) In infiltrating the tissues with local analgesic the needle should be passed under the skin edge, not through the sensitive perineal skin. I use a 2-c.c. syringe fitted with a No. 17 needle for infiltration, and have found this size most convenient.

(2) Before suturing it is a good idea to bathe the wound with proflavine 1 in 1,000 in normal saline, buffered to a *p*H of 6.3.

(3) Surgeons in this war have realized that the smaller the amount of catgut used in wounds the better the healing and the less the chance of infection. Mr. Herbert Haxton (Jan. 13, p. 61) has given an excellent account of the disadvantages of catgut. It has to be used for cervix, vaginal wall, and, sometimes, deep in the perineum. However, it is a good idea to bear in mind that the less catgut employed the better.

(4) For the perineum itself I have found Coats's black cotton thread, No. 10, to be the ideal suture material from every point of view. It should be wrapped loosely on a gauze swab and boiled along with the instruments.

(5) If it is apparent that a perineal repair will take considerable time, the value of premedication should not be forgotten. The mental atmosphere throughout labour should be one of tranquillity and calm, not one of fear and terror. It is the bounden duty of everyone attending women in labour to do their utmost to attain to this end.—I am, etc.,

Edinburgh. JAMES ROSS, M.B., CH.B.

The Harvard System

SIR,—On behalf of many readers like myself who must perforce spend a considerable time in perusing original medical articles and in looking up the references contained therein, I should like to protest against the retention of the so-called "Harvard" system of annotation. Of all possible systems of reference this is surely the worst.

An article is meant primarily to be read as a whole, and only those specially interested will look up the references it contains. From the normal reader's point of view, the "Harvard" system may completely destroy any interest he may have felt on seeing the title of the article. The many authors' names are interspersed in the text like the stones in a cherry pie, and produce mental indigestion unless discarded. I have picked one paragraph at random from the *Journal* of Jan. 27 (p. 116) to illustrate my meaning. I trust that Dr. Berger will not think that I am criticizing his style in any way whatever, but I am only calling attention to the reference system, for which he is in no way responsible.

> Methods for extraction and purification of penicillin are all based on the observation that this substance can be extracted from strongly acidified aqueous solutions into ether, amyl acetate, or chloroform, and re-extracted from the organic solvent into water at *p*H 7 (Clutterbuck *et al.*, 1932; Abraham *et al.*, 1941; Meyer *et al.*, 1942). Further purification is achieved by chromatographic methods (Abraham and Chain, 1942; Catch *et al.*, 1942).

Small superior numerals, thus [3], obviate all distraction from the main theme and serve the same purpose with economy of space, as the "Harvard" system duplicates all the names in an alphabetical list at the end of the article.

Now for the point of view of the "looker-upper." What could be more annoying than trying to find *Brit. med. J.*, 1945, **1**, 116, without the date from a pile of these journals in a box? The date "Jan. 27" solves the problem at once. The volume number sounds simple enough, but in practice is often the reverse. In the first place, it may not be printed on the periodical cover at all, as in the case of the *British Medical Journal*. In other cases several numbers are printed. The current *Lancet* has on the front page "No. IV of Vol. 1, 1945. No. 6335, Vol. CCXLVIII." Why not call it "Jan. 27" and have done?—I am, etc.,

St. Albans, Herts. C. LANGTON HEWER.

⁂ In 1936 the Royal Society held a conference of editors of scientific journals with a view to persuading them to adopt a uniform system of giving bibliographical references to scientific articles. It favoured what it called the "Harvard system," to which Dr. Langton Hewer objects. The following points are thought to be in favour of this system: (1) In the text it gives the reader two relevant pieces of information—the name of the author of a statement, observation, or theory, and the date on which these were published. (2) It makes it easy to assemble the references in alphabetical order at the end of the paper. (3) Additional references can be inserted at the last minute without having to waste time and money in renumbering and in resetting numerous lines of text and references. The example quoted by Dr. Hewer illustrates the one weakness of the system, and in such an article there is something to be said for using superior numerals as indices. Periodicals are eventually bound in numbered volumes and are thus stacked on library shelves—a seemingly good reason for giving the volume number and not the date. We might add here that the origin of the term "Harvard system" is obscure. It was at all events not introduced by Harvard University. It is believed that an English visitor to the library of Harvard University was impressed by the system of bibliographical reference in use there, and dubbed it the "Harvard system" on return to England.—ED., *B.M.J.*

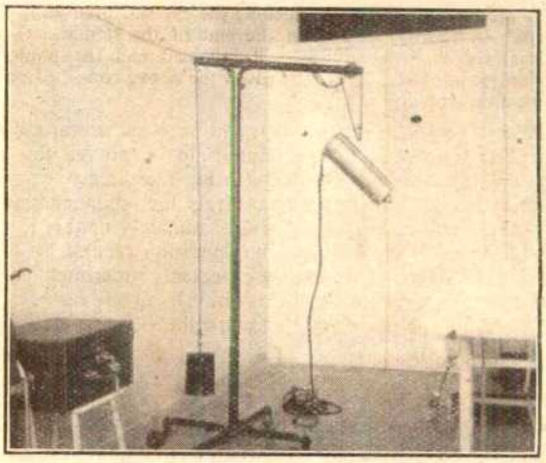
The Giant Magnet in Ophthalmic Battle Casualties

SIR,—In your issue of Nov. 18, 1944, R. E. Wright and H. A. G. Duncan draw timely attention to their experiences with the giant magnet for metallic intraocular foreign bodies in recent battle casualties. The ophthalmologists of the Central Mediterranean Force have had unrivalled experiences during the past two years in the treatment of such cases, and it may possibly be of value at this time to add their conclusions to those of the above commentators.

Magnet Tests.—(*a*) Direct Ophthalmoscopy: It is frequently possible to carry out a giant-magnet test under direct ophthalmoscopy. Thus an impacted foreign body may be seen to rotate in its bed or to rise on the end of a filamentous pedicle to the attraction of the magnetic flux, only to fall back again into position when the current is switched off. This test is the best of all. (*b*) Subjective Response: The negative reaction of the patient to the application of the giant magnet either in the non-anaesthetized or anaesthetized eye is of no value whatsoever. A positive response is of value, but should only be obtained with great caution and with the slow approach of the magnet to the eye; retinal disturbances may be caused or aggravated by repeated magnet applications. (*c*) Direct Vision: Sometimes strong oblique illumination from the head of the ophthalmoscope will show the movement of a foreign body behind the lens in a murky vitreous when the active magnet is applied.

Operation Technique.—(*a*) Since intraocular foreign bodies received in battle are relatively large and ragged the posterior route of extraction is our method of choice. There is no resemblance between these foreign bodies and the smooth flake-like chips received in civil life, which can frequently be wheedled into the anterior chamber prior to extraction. (*b*) As Wright and Duncan point out, the shortest route to the exterior is generally the best. Particularly so is this the case when a foreign body is enmeshed in a pedicle: extraction should then always be through the base of that pedicle and not against it. (*c*) The value of diathermy is still a matter of opinion. Some surgeons say that it causes the scleral wound to gape and may entangle the foreign body in exudate. There is no convincing evidence that retinal detachment is prevented by it or is more frequent without it. Other surgeons say that the risk of haemorrhage is less and that detachment is prevented by the coagulation. There has been no case to date of retinal detachment following uncomplicated posterior sclerotomy in this Force so far as I am aware, but the haemostatic value is considerable. Posterior sclerotomy is considered to be justified in every case of intraocular foreign body, and it is interesting to note that Stallard in his classical article (*Brit. J. Ophthal.*, March, 1944) reports 3 cases in which the foreign body was easily removed by the magnet when there had been no apparent movement ophthalmoscopically to magnetic attraction: these might well have been considered as non-magnetizable foreign bodies had operation not proved otherwise. Nor does every surgeon here use scleral stitches: some claim a simple incision without diathermy heals quickly and gives the best results. (*d*) The composition of a foreign body found in the skin of the face bears no relationship to a foreign body which may be in the eye. Indeed, cases have been reported which had two different kinds of metal, or stone and metal, or different inert foreign bodies in the same eye.

Localization.—In military practice it is not possible or necessary to employ the elaborate methods of peacetime localization technique. In this Force two methods are popular: (i) By the 26-mm. equatorial ring. Skeoch popularized this method, and it has proved of great value. No claim for extreme accuracy is made, but it serves most purposes under war conditions. (ii) By the limbal ring, which we borrowed from our colleagues in the Middle East, where it was introduced by Brigadier Graham. Two lateral shifts and one antero-posterior petrous-free views are taken in each instance.



Magnet Stands.—In the early days many weird and wonderful devices were constructed to carry the Army portable giant magnet; and perhaps the only criticism which could be made, since they all worked, was that they were not sufficiently portable. Now, however, the R.E.M.E. have constructed a simple standard C.M.F. giant magnet stand on the gallows principle, whereby the magnet is suspended on an adjustable wire cable and counterpoise, as shown in the photograph. In this manner the magnet is easily manœuvred to all positions whether the patient is sitting or recumbent. This model is based on a similar pattern designed by Lieut.-Col. Dansey Browning in the Western Desert.

Anaesthesia.—The anaesthesia which has been found to be most suitable for magnet extraction cases is: forward areas, induction by 5% pentothal with continuous 1/2% pentothal drip and oxygen. (It is to be remembered that major surgical procedures may be simultaneous under these conditions); base areas, local analgesia with 4% cocaine drops and subtenon 2% novocain infiltration.

May I conclude, Sir, with the statement that any "follow-up" cards on ophthalmic cases which are returned to this theatre of war will be most gratefully appreciated.—I am, etc.,

B. W. RYCROFT,
A.F.H.Q., C.M.F. Lieut.-Col.; Adviser in Ophthalmology.

Civilian Respirator as Anaesthetic Mask

SIR,—We noted with interest Dr. F. S. Vaughan's adaptation of the gas mask for inhalation anaesthesia (Jan. 27, p. 131). While we do not doubt that as a substitute for Clausen's harness it is all that he claims, we should like to point out that the dead space in the apparatus as illustrated is far too large to permit of adequate CO_2 elimination.

The leakage which Dr. Vaughan advances as a potential criticism of his device is, in our opinion, an essential in preventing the accumulation of CO_2.—We are, etc.,

F. G. ETHERIDGE.
Botleys Park, Chertsey. F. M. SANDFORD.

Nicotinamide Deficiency and Gingivitis

SIR,—I have just read with interest the article by Drs. R. A. Coulson and P. Ellinger and Squad. Ldr. G. A. Smart on urinary elimination of nicotinamide methochloride in subjects with healthy and diseased gums (Jan. 6, p. 6). My interest is accentuated by the fact that in the early summer of 1942 I was asked to make the mouth examinations for the R.A.F. investigation which was then being considered. Indeed, a number of preliminary examinations were made according to plans formulated by Dr. Platt, Dr. Ellinger, Wing Cmdr. Macrae, and myself. A few comments may not, therefore, be out of place here regarding the authors' conclusion that "nicotinamide deficiency probably did not play any part in the development of gingivitis of any type among the subjects examined."

It is difficult, from this paper and from the previous one by Squad. Ldr. Smart, to know what method was used for recording and summarizing the clinical data. On one occasion, I was present when Squad. Ldr. Smart was examining a group of R.A.F. subjects. The condition of the gum surrounding each tooth in the mouth or, in the absence of one or more teeth, the region where the teeth had been was recorded separately. How, then, was the amount of disease estimated per subject? And how were the subjects allotted to the various disease categories described? Was the condition of a mouth assessed as that of the region showing the most severe lesion of a given type, or was some other method adopted?

In the present paper the authors have shown that the amount of physical energy expended is one of the factors which affects the "F_2" content of the urine (Table V). In one of the articles to which they referred (but not in relation to this energy factor) it was stated (King, 1943) that physical exertion seemed to be associated with the onset and progress of ulcerative lesions of the gum. Incidentally, too, no mention is made of the report on acceleration of co-ordinated muscular effort (Frankau, 1943) by nicotinamide. Again, referring to Table V of the present paper, it appears that the higher "F_2" urinary contents occurred in those groups tested during the winter (March), when so-called trench mouth is much more prevalent, and the lower "F_2" values were found in the summer tests (May–June), when the ulcerative disease is relatively rare.

Has any consideration been given to the possible significance of these apparently coincidental observations? In the absence of further investigation, and in view of the admitted lack of knowledge of other factors which may influence urinary elimination of nicotinamide methochloride, are the authors ustified in coming to the conclusion quoted earlier in this etter?—I am, etc.,

J. D. KING, Ph.D., L.D.S.

Psychosomatic Factors in Disease

SIR,—I read with great interest Sir Walter Langdon-Brown's remarks (Jan. 13, p. 35) on the growing importance attached o psychosomatic aspects in modern medicine. Conditions as varied as migraine, angina pectoris, cardiac and bronchial asthma, gastric ulcer, cyclical vomiting, sterility, enuresis, urticaria, and many others are to-day clearly recognized as manifestations of physical, psychological, hereditary, and environmental factors.

But in these days of acute shortage of medical men and women in hospitals and general practice it seems to me that he profession should proceed with great caution. As usual, he truth lies somewhere in the middle. It is just as dangerous o label as neurotic a patient with a real complaint as vice versa. And it should not be forgotten that some chronic onditions of slow and insidious onset—e.g., pulmonary tuberulosis and pernicious anaemia—may present with irritability nd other neurotic symptoms long before any definite clinical igns can be elicited. A careful taking of the family history an be of great help in cases of this sort.

In conclusion I might suggest that we could alter the well-nown Latin proverb to *Mens insana in corpore insano* as a imely reminder and warning.—I am, etc.,

Fazakerley Sanatorium, Liverpool. VICTOR LEITNER.

Psychology's Opportunity

SIR,—The letters of Dr. A. C. Wilson (Jan. 20, p. 96) and Dr. A. Tandy Cannon (Feb. 3, p. 163) give us an astonishingly ptimistic forecast of a world led by psychologists. One is reminded of Auguste Comte's scientific high priests. Their etters, however, raise certain doubts in the mind of the reader.

First, do the therapeutic results achieved by psychologists n actual clinical practice justify the expectation that, however ngenious they may be in describing the aetiological factors in isease, either of the individual or of the body politic, they will rove to be reliable guides in the difficult matter of directing whole communities?

Secondly, is it certain that the social results achieved in Russia *are* due to the guidance of psychologists? There were two very powerful forces shaping society in Russia. One was the fact that ever since the revolution the U.S.S.R. has been faced with the hostility of the world, and, "standing alone" as we did in 1940, neighbourliness was fostered among them, as it was among us at that time. A psychologist should not forget all the fantasy, the projection, and the identification which result from dividing the world into "we" and "they." The real test of the Russian experiment will come when Russia has had ten years of peace and prosperity. And, as international alignments may be quite different by then, it is just conceivable that our views about her aggressiveness may have undergone a subtle change. Another factor in shaping Russian society was the Utopianism which is native to the Russian character, but which finds no justification whatever in the prevailing psychological theory—behaviourism. For the behaviourist all motivation is *a tergo*; for the Utopian it is *a fronte*. You cannot have it both ways.

But apart from these forces there was a very good reason for falling into line with accepted social practice—a reason which had nothing to do with psychologists. We are all Russophile now, of course, and it seems rather ungrateful to recall that like-mindedness in Russia was considerably helped by the "liquidation" of those who were not like-minded. Do the advocates of emulation of Russia suggest similar methods of ensuring social solidarity and conformity in this country?

In the third place, may one ask which school of psychology is going to supply the guides to the new social order—Freudians, Jungians, Adlerians, or Watsonians? Some of these at least are mutually exclusive, even when they are not self-destructive. And, please, Dr. Cannon, is it really true that all psychologists have *ipso facto* no selfish motives?

Fourthly, is it really correct to say that all Western nations are labouring "under the yoke of an archaic ecclesiastical rule"? I should have thought that at no time in the history of the world, except perhaps in Greece in the fifth and fourth centuries B.C., has the Church had less influence on the thought and practice of the masses as at present. Most people pay far more attention to the quite unjustifiably pontifical utterances of scientists or the bletherings of astrologers than they do to the Church leaders. Perhaps that is what is wrong. Who knows?—I am, etc.,

Liverpool. F. B. JULIAN.

Prisoner-of-War Mentality

SIR,—Major P. H. Newman's letter (Feb. 3, p. 163) was of particular interest to me as I read the article quoted while still a P.O.W., and have since experienced the "release phenomena" which he describes.

One has to be very careful in passing comment on this subject in order to avoid the degree of one's "Stalag happiness" being assessed. I should, however, ask Major Newman to consider this question in the light of his experience in contact with: (*a*) psychoneurotics in static units at home; (*b*) repatriates from the West Coast of Africa, Palestine, Iraq, and India; (*c*) civilians outside the "blitzed" areas—i.e., three groups who have seen less action than the majority of P.O.W.s. I think with comparative numbers he will find that the P.O.W. mentality will show up very favourably.

The three enumerated symptoms are as applicable to these groups as they are to P.O.W.s, and surely there is more "lack of respect for authority, actively encouraged disrespect, and sabotage against authority" exhibited among civilian workers than by ex-P.O.W.s or other Servicemen. This is clearly seen by strikes, threats, wilful absenteeism, dictation to national leaders, and so on.

I should also like Major Newman to review the last eight months, and remember the days before D-day: the impatience expressed by everyone, the wave of optimism with the invasion, and the return of the impatience at the Caen delay. This was followed by more rapid progress with fantastic references to the short duration of the war so freely expressed by all except ex-P.O.W.s. Lastly, the attitude adopted by so many of our politicians, press agents, and general public over the Greek question. These are a few of the facts which give me the impression that there is too much fuss made over the mentality of P.O.W.s, and that, with few exceptions, they will not require any more post-war rehabilitation than any other section of the community.

I thoroughly agree with the final paragraph. The "square deal," or lack of it, is, of course, the excuse given for all discontent throughout the country, and unfortunately many ex-P.O.W.s harbour a legitimate grouse.—I am, etc.,

C. DONALD,
Capt., R.A.M.C.

Sulphamerazine

SIR,—I was surprised to read in your leading article on sulphamerazine that this compound is not yet available in this country. It was first supplied to me early in December last, and in 5 cases of lobar pneumonia in which I have used it I have found its clinical effectiveness comparable with that of sulphapyridine. I have had no experience of sulphadiazine, but with sulphamerazine there has been a complete absence of nausea and vomiting and that feeling of malaise which I have found to be almost a constant feature with sulphapyridine and to a slightly lesser degree with sulphathiazole. This absence of toxic symptoms may have been partly due to the fact that I have split the initial dose of 3 g. into two doses of 1½ g., the second dose given 2 hours after the first. Thereafter I have given 1 g. every 8 hours, maintaining this dosage for 72 hours after the temperature and pulse rate had been normal for 24 hours. In this very limited number of cases the temperature has reached normal by the morning of the fourth day, and there has been no subsequent rise. The compound was supplied to me by Messrs. Sharpe and Dohme, Mulford Biological Laboratories, Hoddesdon, Herts.—I am, etc.,

Thrapston, Kettering. E. I. H. WHITE.

Artificial Insemination

SIR,—What are the advantages of artificial (donor) insemination? That the wife probably or possibly produces an offspring and develops a full maternal instinct towards her offspring.

What are the disadvantages? (*a*) The legal aspect, which has already been mentioned in several letters. (*b*) That the procedure requires the donor to masturbate. Although one may accept masturbation as a common occurrence and not the bogy which it was held to be by a previous generation, does the end justify asking a normal healthy man to masturbate, and is there not some risk of it having a psychological effect on the man and disturbing his relationship with his own wife?

The alternative to artificial (donor) insemination is adoption, and in my experience of work in a welfare centre there has been no less maternal instinct aroused in the mother with an adopted baby than in a mother with her own baby, and, in fact, because it has been a baby which has been wanted they have practically without exception been well-cared-for babies.

Approaching sterility from another point of view, is everything being done to prevent women from becoming sterile? Is it not likely, for example, that *x*-ray work over a certain period renders a woman sterile? Three cases are known to me where this has almost certainly been the case—two were radiologists and the third a sister in an *x*-ray department. Should this not be fully investigated, and, if necessary, legislation introduced, either not allowing women to do *x*-ray work without at least warning them of the possible consequences or, if it can be prevented by extra protection, making this compulsory?—I am, etc.,

Dorking, Surrey. MARY C. JEFFRIES.

SIR,—The emotional reaction of most of your correspondents to this subject is rather alarming. In particular, I am amazed at the outlook of Dr. F. M. R. Walshe, who in the past has advocated a medical curriculum designed to attempt to lead the student to think *clearly*. Apparently he would have the student reserve one most important aspect of life—everything pertaining to sex—for emotional consideration only.

Surely, if any body of opinion might be expected to face the physiological-sociological problems of a world intent on permanent peace it is that of the medical profession. Our aim should be to aid the establishment of stable, healthy populations in all the countries of the world, and to this end the possible use of artificial insemination no less than that of birth control should be judged not on grounds of narrow-minded puritanism or bigoted catholicism, or as affecting a patriarchal property-owning society, but with a view to the greater security and happiness of the ordinary man—I am, etc.

London, W.1. M. GRACE EGGLETON.

SIR,—Whatever may be one's personal views on the above subject, it is right and proper that the opinions of the profession should be ventilated as widely as possible in the columns of the *Journal*. That the opinions are diverse is evident, and those who support the operation do so largely for two reasons: (1) to satisfy the parental longings of the childless but otherwise happily married couple; and (2) to increase the number of children born, and thereby rescue the nation from steady progressive extinction in the role of world man-power.

I agree with Dr. Leonard G. Parsons (Jan. 20, p. 96) that the first of these is adequately provided for in the adoption of children. This has the advantage that the child can be selected by husband and wife after searching inquiry on the part of the Adoption Society, and that the existence of congenital disease or inherent weakness in the child can be almost completely eliminated by competent examination of the child and evidence of the sound health of its parents. Dr. C. O. Carter (Jan. 27, p. 130) urges the advisability of artificial insemination in cases where "a woman is unable to find a husband"—surplus of women over men of reproductive age after the war. This, it is presumed, includes all spinsters and widows of reproductive age. Does Dr. Carter believe that legalized artificial insemination for this purpose would be followed by the picture of queues of eligible spinsters and young widows at the consulting-rooms of obstetricians and gynaecologists? Surely not! Rather than pretend that artificial insemination is the answer to this problem, would it not be at least as ethical to legalize polygamy for the virile husband and sterile wife, and abolish the Seventh Commandment in favour of the woman so unfortunately mated to an impotent husband?

Why has the profession not the considered opinion and guidance of the Royal College of Obstetricians and Gynaecologists and why the silence of the Christian Church? None the less important in influencing the practice of this revolutionary operation would be the views of the Law Lords on its legality.

The whole idea must be so repellent to the average individual that to its advocates the great mass may exclaim in amazement "What sort of people do they think we are?"—I am, etc.,

London, S.W.1. A. S. HANNAY.

SIR,—Having read some letters in your *Journal* on this subject with disgust, I was more than pleased to read those of Dr. Leonard Parsons (Jan. 20, p. 96) and Dr. F. M. R. Walshe and others (Feb. 3, p. 165). It is to be hoped that those who advocate this practice will consider whether or not they are accessories before the act to pseudo-adulterous practices, and that these result in illegitimate babies for all time. This practice, with its results, cannot be defended on religious, moral or even eugenic grounds. It may well be that the General Medical Council will come to regard this as "unprofessional conduct," and it would be well if it did.—I am, etc.,

London, W.1. C. GORDON-WATSON.

SIR,—Your recent correspondents have shown much indignation against the practice of human artificial insemination. The legal position, the Christian ethic, the social consequences and even natural delicacy have all been invoked as strong reasons against that practice. Without challenging the legal argument or entering into a discussion of the social precedent involved, I think it would be fair to suggest that your correspondents have, in the full flush of their righteousness, somewhat lost their sense of proportion. Facts need re-emphasis. Artificial insemination is proposed only for that comparatively small but very unfortunate minority of couples who are sterile due to some fault in the husband's sperm or to incompatibility between otherwise normal gametes, and who also ardently desire a fruitful marriage. Lurid pictures of vast stud farms and the imaginary scenes within are the product of a prurient rather than a reasonable mind.

Those who cry for a greater awareness of Christian principle should remember that human compassion is a Christian recept, perhaps the greatest of them, and there is almost no agedy so great as that of a childless marriage between those ho love children. Our compassion, not our indignation, should e aroused by these people who want children at least half-kin themselves. Further, it should be remembered that in olden mes, and still in many of the great agricultural areas of urope, the hollow mockery of a childless marriage is avoided y society's tacit sanction of pregnancy before marriage. Modern civilization would not tolerate that; no more will it olerate marriage at a reasonably early age; it is in fact so far rom Nature in its social laws that human attempts at compensation are inevitable. The doctor's attitude in the face of is conflict is indeed difficult, but surely a pharisaical attitude hould be avoided. As in the case of many other medical thical problems the best plan is to avoid pronouncements, ut to keep one's own counsel and a clear conscience.—am, etc.,

"SERVICE DOCTOR."

Deaf Aids

SIR,—I have during the past ten or so years had some experience of the various types of deaf aids in an attempt to find uitable apparatus for the individual use of deaf children for ducational work, and for various adults who have enlisted y help in the matter. I can only conclude that the circumances of wartime plus a patch of bad luck are the reasons or the excessive maintenance costs of Mrs. Barlow's various eaf aids (Jan. 27, p. 130), as I can find no one among my cquaintance who has had anything like the amount of trouble, hen using pre-war apparatus, now from six to nine or more ears old. The quality of accumulators and batteries has ndeniably gone down, as some of the essential ingredients are short supply, but the failures of valves can only be put own to faulty inspection or constructional weaknesses, which re the responsibility of the valve-making firm and not of the akers or assemblers of deaf aids.

The greatest trouble with the deaf aid of any type is the perennial tempt to get a quart into a pint pot, so as to render the apparatus small and compact as possible. Thus the sizes of components e reduced to the minimum, and so the margin of material strength d insulation, etc., is reduced beyond that required for real urability and longevity. In the specific cases of the H.T. battery d L.T. accumulator, the reduction in size and weight inevitably eans a reduction in metal and chemicals needed to produce or ore electrical energy, so that a good current capacity is impossible. he relationship between life and weight is roughly a geometrical ogression, so that the tiny batteries in use are obviously not meant last more than a short time in constant activity.

The need to return apparatus to London for repair is also parently a wartime necessity, for in peacetime most of the reputble dealers had provincial depots to relieve the user of the delays far as possible. It is, however, possible that the makers wish handle their own apparatus, not merely from the business point view, but in order to secure that the repairs are done properly r the sake of the repute of their products. In post-war days when dio servicing returns to its previous high level, there will be ample cilities in every town of any size for the instant repair of any ad aid, provided that the parts needed are such as are reasonably andard in the trade. There is no difference between the inside a deaf aid and the low-frequency end of a wireless set, and it n as easily be tested and repaired.

The other points mentioned by Mrs. Barlow may be briefly swered thus: (1) A standard or utility deaf-aid set, battery only, n be built now at home by anyone used to simple tools, on the sis of the design by Dr. Littler, published some time ago in the *ireless World*, with lists of parts and full instructions. (2) Directns for the conversion of an all-electric "midget" receiver into a od-quality deaf aid were given in an American periodical early the present war, and the job is fairly straightforward. (3) The rections for the making up of a miniature three-valve pocketable af aid are available from U.S. sources, and if any doctor would e a copy I can supply one if given the necessary time for reproction. (I have recently supplied one gratis to an assistant M.O.H.) A good all-mains deaf aid can be adapted from a mains amplifier the incorporation of a crystal microphone and suitable ear-piece, the use of the gramophone amplified end of a modern wireless , using the extra loudspeaker wiring to carry the ear-piece wiring, bject to the usual safety precautions for electricity.

Economy can be made in running costs in the following ways, all which have been practically tested over a period of years.

Non-valve Aids.—Use that battery which is heaviest, for it gives ngest service, and use three or four in series to recuperate. Switch the current whenever the aid is out of use, for the current pits" the granules or balls of carbon in the usual microphone, necessitating replacements. Treat the connecting cords very carefully, keeping them away from perspiration so far as possible, and remember that a kink in the cord may be a break later. If batteries are expensive or hard to get, secure some U.2 size cells and make a small container to take the required number in series to make 3, 4½, or 6 volts' supply.

Valve Aids.—If the aid is to be used at any time in a stationary position for hours at a time, it is a great economy to use a heavy-duty high-tension battery of 120 volts and a large 2-volt accumulator, external to the aid by means of short wires and clips. The first 60 volts are used one day and the second 60 the next day and so on. Six to nine months' use can be expected from a good battery, and a box can be designed as a base for the deaf aid to stand on and contain the batteries when so used. Finally the use of a hydrometer and a trickle charger with two accumulators, kept properly charged and used in turn, will extend the life of the usual small accumulator by a considerable amount.—I am, etc.,

EDWARD T. JORDAN,
Honours Diploma, College of
Teachers of the Deaf.

935, Great Cambridge Road, Enfield.

The Younger Men

SIR,—Mr. A. Basil Rooke's letter (Jan. 20, p. 97) calls for comment on several grounds. My letter did not refer to E.M.S. officers but to A.M.O.s of permanent institutions, nor did it refer only to younger men. We are not asking for amenities but for an opportunity to live normal lives despite the fact that we have taken up hospital work. Many of us, working in hospitals where there is a gross shortage of medical and nursing staff, have not been able to "continue our studies." The authorities, however willing, have been unable to give us facilities. In many cases serving officers have had varied experience which will be invaluable not only in practice but in obtaining higher diplomas.

He fails, apparently, to realize that if the advances urged in my letter are made, serving officers who come into hospital practice will benefit thereby. It is not unknown for an A.M.O., who has married while on service, to be threatened with the loss of his reinstatement rights. Many of the younger men on service, who will wish to study further, are already married and deserve "at least as good a chance as their contemporaries" of continuing (beginning might be more accurate) a normal married life. In the majority of hospitals this is an utter impossibility. I would refer him to the *Journal* of Nov. 4 (p. 610) for a medical superintendent's views on this.

His unfortunate references to "those who enlisted" and "those who obtained further deferment" are to be deprecated. Apart from those rejected by the Services on medical grounds, there are many who have made repeated attempts to volunteer and who have been refused permission to leave their posts or whose call-up has been successfully opposed by the Departments controlling their hospitals. With the probable increase in resident posts after the war there should be room for all who have served loyally at home or over-seas—in uniform or out. Nothing has been written which invalidates the arguments for, or lessens the urgency of, providing proper quarters for A.M.O.s. "Both the future of medicine and eugenic considerations" urge "the need for such a step."—I am, etc.,

"B1."

Neurone, Mind, and Crime

SIR,—Without here discussing other controversial points raised in your annotation on Prof. R. J. A. Berry's address (Feb. 3, p. 157) I should like to suggest that his observations on the brains and skulls of criminals be accepted with considerable reserve. In his original article Prof. Berry states that, with regard to the size and weight of the brain, "50% of the habitual criminal classes approximate more nearly to mentally defective levels than to the normal—that is, they have underdeveloped supragranular brains of control." Further, with regard to skull capacities, he states that these are largest in "university teachers," "followed on a downward scale by such different mental types as . . . criminals, 20-year-old reformatory boys, 13-year-old mentally defective boys," etc.

Since the days of Lombroso a vast amount of scientific evidence has been accumulated tending to disprove the validity of alleged physical anthropological characteristics by which the so-called "criminal" and the "reformatory boy" could be differentiated as specific types from the "rest" of the population. Prof. Berry's findings, based on statistical studies of isolated groups of so-called "criminals," should therefore be considered extremely critically, particularly with regard to such points as selection of cases and "controls," their intelligence, physical history, etc. C. Goring, as early as 1913, wrote: "There is no such thing as a physical criminal type"; and many other authorities, including the eminent anthropologist Hrdlicka, are in complete agreement with this statement.

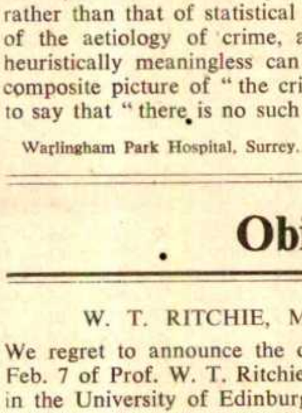
Although it would no doubt be a conveniently simple explanation of criminality to regard it, with Prof. Berry, as being due to an underdeveloped supragranular cortical level and, therefore, to uninhibited infragranular activity, there is as yet insufficient evidence to justify this conclusion. Indeed, recent research in psychopathology has shown how near to overt criminal activity we all may be—"university teachers" no less than the feeble-minded, and probably more so, for intelligence, however misdirected, is often necessary to commit a crime. Criminal psychopathology in particular, as represented by the work of Healy, Alexander, Aichhorn, Karpman, and others, has stressed the importance of a study of the *individual*, rather than that of statistical generalities, in the understanding of the aetiology of crime, and has gone far to show how heuristically meaningless can be the study of an average or composite picture of "the criminal." One might go so far as to say that "there is no such animal."—I am, etc.,

Warlingham Park Hospital, Surrey. R. H. AHRENFELDT.

Obituary

W. T. RITCHIE, M.D., LL.D., F.R.C.P.ED.

We regret to announce the death at Colinton, Edinburgh, on Feb. 7 of Prof. W. T. Ritchie, who held the chair of medicine in the University of Edinburgh for ten years, and was elected President of the Royal College of Physicians of Edinburgh in 1935. He was well known for his work in cardiology, published a monograph on auricular flutter in 1914, and delivered the St. Cyres Lecture in London in 1939; his book on *Diseases of the Heart*, written jointly with Dr. John Cowan, of Glasgow, reached a third edition.



[Photo by Young, Edinburgh

William Thomas Ritchie, son of R. B. Ritchie, was born on Nov. 3, 1873, and studied medicine at the University of Edinburgh, taking the degrees of M.B., C.M. in 1896, and the M.D. in 1899, and was elected F.R.C.P.Ed. in 1903. After graduation he studied in Vienna clinics, and returning to Edinburgh practised there for over 40 years. He became physician, and later consulting physician, to the Royal Infirmary and to the Deaconess Hospital, and physician consultant to the Edinburgh municipal hospitals. During the last war he was at first medical officer to the 1/3 Scottish Horse and later in charge of the medical division of No. 27 General Hospital in Egypt. His war services were recognized by mention in dispatches and the award of the O.B.E. In the present war he acted as physician at the Emergency Medical Service Hospital at Bangour, and he had been honorary consultant in cardiovascular cases for the Ministry of Pensions.

When W. T. Ritchie succeeded Prof. Lovell Gulland in the chair of medicine at Edinburgh in 1928 he took a large part in remodelling the arrangements for teaching in the Faculty of Medicine by co-ordination of the courses given by the professors of pathology, materia medica, medicine, and surgery. He was a Fellow of the Association of Physicians of Great Britain and Ireland and of the Royal Society of Edinburgh, and gave the Gibson Memorial Lectures in 1923. His services as an examiner in medicine were called upon by the Universities of St. Andrews, Aberdeen, and Durham. In the British Medical Association he held office as secretary of the Section of Medicine at Newcastle in 1921 and as vice-president during the Edinburgh Annual Meeting of 1927. Last year he receiv from his own university the honorary degree of LL.D. Besid his writings on diseases of the heart Prof. Ritchie was joi author with Dr. J. J. Graham Brown of a book on *Medic Diagnosis*, which passed into a fifth edition and was deservec popular as a handbook of clinical methods for practitione and students.

KATHLEEN KITCHIN, M.B., M.Sc.

We announce with much regret the death after a short illn of Dr. Kathleen Kitchin on Feb. 5 at Aldbourne, Wiltshi For some years she took an active part in B.M.A. work representative of her Division, and her literary gift found outlet in the service of medical and legal journals and authors of many papers and books.

Mary Kathleen Forsaith Lander was born at Bournemou on May 21, 1897, and from Wimbledon High School went study for our profession at the London School of Medici for Women and St. Mary's Hospital. Before qualifying M. B.S.Lond. in 1921 she had been demonstrator of anato at the London School of Medicine for Women and honor acting prosector for the Zoological Society. She was the fi woman to take the B.Sc.Lond. degree in human anatomy morphology, following it in 1919 with the M.Sc. She awarded a Beit Fellowship in 1921, but had to resign it account of ill-health. After acting as assistant curator of Wellcome Historical Medical Museum she had five years general practice in London, including infant welfare and ar natal clinics. She was a member of the Representative Bc of the B.M.A. from 1923 to 1928 and vice-chairman of St. Pancras Division in 1926. She began psychological stu in 1923, working with Jung in Zurich, and was on the st of the Tavistock Clinic for some time, working also at Bethlem and the Maudsley Hospitals. In 1925 Dr. Lan married Mr. D. Harcourt Kitchin, barrister-at-law and frequent contributor to these columns, and she herself called to the Bar in 1936. Together and separately they a great deal of legal and medical journalism, and transla and edited a number of books for medical authors.

During the last few years Dr. Kathleen Kitchin worl chiefly as a psychologist, and took special interest in the Gu of Pastoral Therapy. Her enterprise and thoroughness varied directions did not seem to exhaust the fund of nat energy or the zest for life, and her passing at the age of leaves a gap in a wide circle of friends and colleagues.

CECIL A. JOLL, F.R.C.S.

Surg. Rear-Adml. G. GORDON-TAYLOR writes: Perhaps a b space may be permitted to one who, though not a hosp colleague of Cecil Joll, greatly admired his surgery and courage. Reference has already been made to his colo industry and energy, but no one has affirmed the truth no other operating surgeon within our British Isles can h completed so vast a number of major surgical operations a lifetime of scarcely 60 years.

Joll drove the chariot of his professional life with incredible sp with ceaseless wheels, and without rein or bridle. The obitu notice in your columns has remarked on the astronomic numbe hospitals to which he was attached and the legendary list of op tions performed at each séance; and Joll's attachment to hospital was not a mere nominal affixation but involved a wh hearted participation in the surgical work of the institution. surgical life was one of deeds rather than words, and it is a consummate surgical artist that he himself would have desired tc remembered. There are a few operating theatres in London to w a surgical visit becomes an inevitability; in Joll's theatre there an assurance of a goodly surgical company—not the surg wanderer on a busman's holiday, but busy surgeons anxious improve their own art.

The fortitude and courage wherewith he continued his opera work under a sentence of death until a fortnight of his demise c manded the respect and admiration of all; the carefully corre and signed letter the day before his death recalls the story of Venerable Bede, and the words used by the great Marquis Montrose three hundred years ago keep recurring to one's li "I am resolved to carry on with honour and fidelity to the gra

He was not the only member of our profession to interest him in ornithology, and on the few occasions when he tore himself a from his ceaseless surgical life he would transport himself to s bird sanctuary or island off the shore, where he could observe avian friends. It seemed not unfitting that a great concourse of birds which the duress of the weather had driven inland and which gathered in flocks in the neighbourhood of his domicile should be present at the passing of one who had loved them so devotedly in the noontide of his eager, ardent life.

Mr. Robert V. Cooke, Ch.M., F.R.C.S., writes:

For many of us in the Provinces the untimely death of this great surgeon is a cruel blow. We have with so much profit spent wonderful afternoons with him, even though we may have been humbled by the experience. We shall always feel very much gratitude for surgical instruction and inspiration, and some of us for much personal kindliness and hospitality, so that there is a special poignancy attached to his passing. These remarks would be reiterated by vast numbers of surgeons from other countries—and particularly by our American colleagues. (I shall never forget the eulogies of both Mr. Willie and Mr. Charlie Mayo.) Joll would discourse so well to a crowd of visiting surgeons, though operating all the time at incredible speed with such enviable precision and accuracy. One must speak of his team work, particularly as it was seen on those Monday afternoons at the Royal Free Hospital. The fineness of his work, his drive and tirelessness, were only matched by the loyal, unsparing energies of the anaesthetists and his many assistants—by no means forgetting the sisters and nurses in the theatres and in the wards. He was always ready to give generous praise to those who had contributed to his success. Others have tried to emphasize his phenomenal capacity for sustained work of the highest order which must undoubtedly become legendary. He was truly a magnificent surgeon. In our ranks few, if any, can have accomplished so much so well.

We regret to announce the death on Jan. 16 in a nursing home, after a short illness, of Dr. R. W. H. Meredith, formerly of Wellington, Somerset, aged 70. He studied medicine at the Middlesex Hospital, and after qualifying M.R.C.S., L.R.C.P. in 1900 was house-surgeon to the Seamen's Hospital, Greenwich. During the last war he served as captain, R.A.M.C., with the 121st Indian Combined Field Ambulance, B.E.F. Dr. Meredith was for many years medical officer to Wellington School and surgeon to the local cottage hospital. He joined the B.M.A. in 1906 and held office as president of the West Somerset Branch in 1919–20. Latterly he had lived in retirement at Bournemouth.

Dr. Thomas Rowland Charles Whipham, who died at Exeter on Jan. 20, was the son of Thomas T. Whipham, M.D., and was born in London on Jan. 4, 1871. He was educated at Rugby School and New College, Oxford, and at St. George's Hospital, where his father was physician. He graduated M.B., B.Ch.Oxon in 1898, took the M.R.C.P. in 1900, and proceeded M.A. and M.D. in 1905. At St. George's he served as demonstrator in materia medica, assistant curator of the museum, and medical registrar; later he became physician to the Evelina Hospital for Children, and assistant physician and physician-in-charge of the children's department of the Prince of Wales's Hospital, Tottenham. In 1918 he gave up work in London and went to South Devon, where, though nominally in retirement, he acted as assistant physician to the Royal Devon and Exeter Hospital, and consulting physician to the Exeter Dispensary and the Children's Convalescent Home at Exmouth. His manual on *Medical Diseases of Children* was published in 1912, and about that time he wrote a number of papers which appeared in this and other journals.

The death of Leonard West of Hoddesdon, Herts, at the age of 65, on Jan. 27 has taken away a notable medical landmark from East Herts. Born at Leeds, he was educated at Carglefield, Fettes, and Edinburgh University, where he graduated in 1903. He came to Hoddesdon in 1907, first as assistant and later for many years as head of a large town and country practice, where he was widely known and greatly liked. He held a number of appointments—as medical officer to the police, railway, and post office—and for over 20 years was honorary physician to the Hertford County Hospital. Later, he was made a J.P. and also a local councillor. He was also chairman or president of practically every club or association in the district. In all branches of work he showed the same buoyant energy, wise counsel, and ready understanding. He was a big man with a big heart, and will long be affectionately remembered by his many patients and friends —the terms are synonymous—for the outstanding feature of his life's work was his deep humanity. He had indeed a real flair for friendship. With old and young, rich and poor, he was always the personal friend as well as the doctor. His carefulness combined with his geniality and sense of humour, the twinkle in his eye, the jolly laugh, all inspired confidence, hope, and a feeling of security, and made him a welcome visitor to every house. As a physician he belonged perhaps to the older school of practitioners, who never forgot the patient in the case, and who placed clinical examination and diagnosis first, with laboratory methods an essential and invaluable adjunct. In midwifery his long experience had made him a first-rate accoucheur, and many families of two generations are indebted to him for his skilful and patient help. During the 1914–18 war he served as captain, R.A.M.C., in Egypt, Palestine, and Gallipoli; in this war he was head of the local first-aid post, which owed so much to him in its foundation and development, as well as to the enthusiastic support he aroused in those under him. In spite of his manifold activities he was a modest man, rarely spoke in public, and never advertised. He may not be remembered for original research work or surgical technique, but he will be long cherished in the hearts of all those who knew him for his strong and persuasive personality. In private life he was a splendid companion, and was always the life and soul of any gathering. He took a keen and active interest in all forms of outdoor pursuits: in his early days a famous rugger forward (he played for Scotland for three years, and was captain in 1906), a good shot and fisherman, and a good gardener (especially in rock plants). Indeed all sports appealed to him, though in later years recurrent illnesses limited these activities, but his interests were maintained, and he never complained. He lived greatly, he died bravely. Our deep sympathy goes to his wife, daughter, and two sons, both serving now in India.—L. R. L.

Dr. Edward Stanley Robinson, who died at Stourport-on-Severn on Feb. 2, aged 79, was born at Leicester, son of George and Sarah Robinson. On the death of his father the small family removed to Stourport and lived for many years in Lombard Street in what is now the Workman's Club, and from there he went to the London Hospital, qualifying M.R.C.S., L.R.C.P. in 1888. For some years he voyaged round the world before settling down to what was to be his life's work—a family doctor—until his retirement in 1939. He joined the B.M.A. in 1899 and had been president of the Midland Branch of the Society of Medical Officers of Health. A correspondent writes: Dr. Robinson's was a long life and a full life. It was, above all, an unselfish life, and, as he always averred, a happy one. It was sufficient that he could serve his fellow men, and his reward was abundant in the boundless trust and affection given him not only by his patients but by all those among whom his lot was cast.

Dr. Thomas Torrens McKendry died on Feb. 3 at the age of 82 after an illness lasting seven years. Born at Clough, County Antrim, he was educated at Coleraine Academy, Ballymena; at Queen's College, Cork, where he took his B.A. in science; and at Queen's College, Belfast, where he studied medicine, graduating M.B., B.Ch., and B.A.O. in 1894. Having worked as an assistant in Dulwich and Ilford he had his own practice in Goodmayes for some 19 years. At the end of 1918 he suffered a breakdown in health and relinquished his practice, but until 1927 he helped several of his medical friends in Buckinghamshire during the summer periods. Dr. McKendry was an ardent devotee of all kinds of outdoor sport, and performed many charitable acts in an unassuming way; one of his last gifts was £500 to the Old Boys' Association of Coleraine Academy for the prize fund.

Dr. John Robert Walker died at Hove on Feb. 3 in his 100th year. The son of a doctor, he went from Kensington School to Epsom College as its first pupil. He studied medicine at St. Mary's Hospital, and after qualifying in 1868 served as house-surgeon and resident obstetrical officer there; his next appointment was as resident surgeon at Jarrow Infirmary. After that he took up practice in North-West London and was honorary surgeon to St. Peter's Home, Kilburn, and to the N.W. Division of the Metropolitan Police. Dr. Walker was the oldest Red Cross surgeon, and recently had a letter of congratulation from H.R.H. the Duke of Gloucester. The French Sisters of Mercy presented him with a Bible after the siege of Metz for his devotion to the wounded, and he held the German medal of the war of 1870–1. He joined the B.M.A. in 1873 and remained a member until his final retirement from practice. Dr. Walker's hopeful outlook on life helped him to maintain good health and reach his great age. He was a keen sportsman and noted for his love of Nature. He will be much missed by all who knew him.

Mr. A. R. Jordan writes: With great regret I read in your issue of Jan. 27 the obituary notice of Mr. Ferrier Walters of Bristol. The statement that in 1916 he was in charge of the abdominal centre at Aveluy is not correct. His centre was at Warloy-Baillon, behind Albert, where I had the pleasure of being one of the surgeons under him. We published the then largest series of abdominal wound cases, and here Walters had the honour of taking King George V round his hospital.

The Services

The Institute of Aeronautical Sciences of the United States has presented to Air Marshal Sir Harold Whittingham, Director-General of the R.A.F. Medical Services, its John Jeffries award for 1944.

Temp. Surg. Lieut. G. J. Potts, R.N.V.R., has been mentioned in dispatches for gallantry, determination, and devotion to duty in the assault on and capture of the island of Walcheren.

Lieut. K. C. Stephenson, R.A.M.C., and Jamadar R. D. Chowdhury, I.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in Italy.

Capt. J. R. O. Thompson, R.A.M.C., has been posthumously awarded the George Cross in recognition of most conspicuous gallantry in carrying out hazardous work. The citation reads:

> The award is for conspicuous gallantry and devotion to duty on board hospital ships since the start of the war, notably on the *Paris* at Dunkirk in May, 1940, and on the *St. David* at Sicily, Salerno, and at Anzio, when in each instance, in spite of repeated dive-bombing attacks and enemy shell-fire, he showed indifference to danger and physical exhaustion in the care of his patients. At Anzio on the night of Jan. 24, 1944, when the *St. David* was sinking rapidly as the result of a direct bomb-hit, he organized parties to carry the seriously wounded to safety in the boats and was thus instrumental in saving many lives. When the ship was obviously about to founder and all were ordered to save themselves, he returned alone in a last effort to save the one remaining helpless patient still lying trapped below. It is presumed that Capt. Thompson went down with the ship.

The *London Gazette* has announced the following appointments, awards, and mentions in recognition of gallant and distinguished services in North-West Europe:

C.B.E. (Military Division).—Brigs. (Temp.) H. L. G. Hughes, D.S.O., M.C., R.A.M.C., Reserve of Officers, A. E. Porritt, O.B.E., and Q. V. B. Wallace, O.B.E., M.C., R.A.M.C.

O.B.E. (Military Division).—Cols. (Temp.) R. D. Cameron, M.C., and K. A. MacD. Tomory, R.A.M.C., and C. Helm, D.S.O., M.C., R.A.M.C., Reserve of Officers; Majors (Temp. Lieut.-Cols.) E. Catford, W. M. Evans, M.C., L. R. H. Keatinge, S. C. H. Lane, A. MacLennan, P. R. Mitchell, and I am M. Paton, R.A.M.C., Col. B. C. Leech, and Lieut.-Col. (Acting Col.) C. D. Gossage, R.C.A.M.C.

M.B.E. (Military Division).—Major (Temp. Lieut.-Col.) W. S. Harvey; Capts. (Temp. Majors) F. J. S. Bowman, N. R. Butcher, F. O'K. Craven, H. Kennedy, R. L. MacPherson, and H. K. Meller; Capt. F. R. B. H. Kennedy, R.A.M.C.; Majors J. G. Jose, J. C. Luke, and R. A. Mustard, R.C.A.M.C.

D.S.O.—Major (Temp. Lieut.-Col.) A. McC. Campbell, R.A.M.C.

Bar to the M.C.—Capt. F. W. Hayter, M.C., R.C.A.M.C.

M.C.—Capts. P. W. Henderson, J. Johnston, and J. M. Murphy, R.A.M.C. Capts. H. L. Handford and W. S. Huckvale, R.C.A.M.C.

Mentioned in Dispatches.—Col. (Temp.) C. E. Eccles, O.B.E., and Major (Temp. Lieut.-Col.) C. D. Evans, O.B.E., R.A.M.C.

The *London Gazette* has announced the following appointments, awards, and mentions in recognition of gallant and distinguished services in Italy:

O.B.E. (Military Division).—Col. C. S. Thompson; Lieut.-Cols. J. P. Laplante and J. A. Noble, R.C.A.M.C.

M.B.E. (Military Division).—Majors J. L. M. Anderson, A. M. Doyle, and P. A. Scott, R.C.A.M.C.

D.S.O.—Col. H. M. Elder, R.C.A.M.C.

Mentioned in Dispatches.—Col. G. A. Sinclair, Lieut.-Col. J. H. Palmer, Majors G. M. Bastedo, J. K. Bell, J. A. Bradshaw, D. R. E. MacLeod, E. A. MacNaughton, P. J. Maloney, J. A. Melanson, E. Quehl, L. J. Quinn, J. G. Shannon, F. L. Shipp, P. M. Spence, A. R. Tanner, and P. K. Tisdale, Capts. G. C. Bowes, J. A. Gow and T. Statten, R.C.A.M.C.

The *London Gazette* has announced the following appointments and awards in recognition of gallant and distinguished services in Burma and on the Eastern Frontier of India:

O.B.E. (Military Division).—Cols. (Temp.) R. A. Anderson and W. J. Officer; Majors (Temp. Lieut.-Cols.) J. A. Baty, J. G. M. A. Brunet, A. D. Davidson, M. H.-P. Sayers; Capt. (Temp. Major) A. E. Jowett, R.A.M.C.

M.B.E. (Military Division).—Capts. H. M. Jamison and K. McCaul, R.A.M.C.; Capt. L. N. B. Raja and Subadars D. Mohd and L. Ram, I.A.M.C.

M.C.—Capt. (Temp. Major) (Acting Lieut.-Col.) A. Burns, and Capts. J. W. R. Battram and D. Mitchell, R.A.M.C.; Capt. (Temp. Major) U. S. Sidhu, Capts. K. C. D. Gupta and P. C. Sarkar, Lieut. (Acting Capt.) B. G. Kiddle, and Subadar S. Singh, I.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Killed in action in Burma.—Capt. John Ravenhill Sweeting, R.A.M.C.

Killed as the result of an accident, while on active service.—War Subs. Capt. Gerald Arthur Richards, R.A.M.C.

Wounded.—War Subs. Capt. S. D. Stock, O.B.E., R.A.M.C.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on Feb. 6 the University accepted gratefully from the Rockefeller Foundation £1,200 for biochemical investigations of penicillin during the year beginning March 1, under the direction of the professor of pathology, Sir Howard Florey.

In a Congregation held on Jan. 25 the following medical degrees were conferred:

D.M.—*W. A. Young.

B.M., B.Ch.—N. D. Ashe, M. J. T. Hewetson, *A. G. Beckett, *M. R. Williams, *J. T. Wright, *B. A. Ellenberg.

* In absence.

UNIVERSITY OF LONDON

The following have been recognized as teachers of the University in the subjects indicated in parenthesis: *Lister Institute of Preventive Medicine:* Dr. A. N. Drury, F.R.S. (Pathology). *University College:* Dr. R. A. Gregory (Physiology); Dr. H. O. Schild (Pharmacology). *St. Thomas's Hospital Medical School:* Dr. C. C. N. Vass (Physiology). *St. George's Hospital Medical School:* Mr. J. R. Peacock, F.R.C.S. (Oto-rhino-laryngology). *London Hospital Medical College:* Mr. R. W. Watson-Jones, F.R.C.S. (Orthopaedics); Dr. H. L. Wilson, F.R.C.P. (Mental Diseases). *Royal Veterinary College:* Dr. E. C. Amoroso (Histology and Embryology).

In and after 1945 the first examination for medical degrees held in December will be normally open only to the following: (1) Candidates who have been "referred" in one subject at a previous examination. (2) Candidates exempted from one or two subjects of the examination. (3) Candidates who produce a medical certificate that they were prevented by ill-health from sitting for the examination in the previous July.

UNIVERSITY OF MANCHESTER

Brian Schofield, M.B., B.Chir., has been appointed demonstrator in human physiology, and N. J. Caldwell, L.M.S.S.A., demonstrator in pathology.

UNIVERSITY OF SHEFFIELD

The Council of the University has accepted, with great regret, the resignation of Mr. George Wilkinson, M.B., F.R.C.S., of his post of Lecturer in the History of Medicine, and has thanked him for his valuable services to the University and its forerunners over a period of 51 years.

The Council has made the following appointments: Honorary Lecturer in the History of Medicine, Prof. E. F. Finch, M.D., F.R.C.S.; Temporary Demonstrator in Anatomy, W. J. W. Sharrard, M.B., Ch.B.; Honorary Lecturer in Psychology in the Faculty of Medicine, J. Carson, M.B., Ch.B.; Tutor for Diseases of Children, C. H. Rosenberg, M.B., Ch.B.

QUEEN'S UNIVERSITY, BELFAST

The following candidates have been approved at the examination indicated:

M.B., B.Ch., B.A.O.—*H. F. W. Fry, †J. H. Bruce, †T. T. Fulton, †W. McG. Lowry, †W. H. McDaniel, †J. K. Morrison, †M. W. Wilkin, J. T. Boyd, H. E. Busby, M. Byrne, R. S. Casement, W. F. Colburn, Sheelah B. Cosgrove, F. C. McC. Coyne, Eileen M. Craven, T. H. G. Dick, W. J. Elwood, T. P. Fearis, D. T. Gilchrist, C. J. Gilligan, W. A. Gilmore, G. T. C. Hamilton, F. E. Henderson, F. D. Honneyman, J. C. S. Houston, J. K. Hunter, Lucy M. Hunter, D. B. Kenny, Sophia E. Kernohan, Kathleen M. King, A. Kirkpatrick, Mary A. H. Lawson, Patricia M. Leitch, C. G. Lowry, H. D. C. McCaldin, S. G. McComb, J. A. McHugh, O. K. B. Moreland, Claire E. Morris, B. Mullally, R. A. Nelly, W. J. Patterson, T. W. Roddie, Gladys G. Seymour, M. McK. Shaw, J. T. Shepherd, Elizabeth Sherrard, Jessie H. Sloan, B. T. Smyth, J. Stewart, D. H. Tweedie, A. L. Wells, Mary Williams, P. J. K. Wilson, R. D. Wright.

* With first-class honours. † With second-class honours.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Professional lectures on applied physiology, by Prof. John Beattie, at 2.30 p.m., and on anatomy, by Prof. A. J. E. Cave, at 4 p.m., will be delivered at the College, Lincoln's Inn Fields, W.C., on Mondays, Wednesdays, and Fridays, from Feb. 19 to March 16 inclusive. Details will be published in the diary column of the *Supplement* week by week.

At an ordinary meeting of the Council on Feb. 8, with Sir Alfred Webb-Johnson, President, in the chair, resolutions of condolence were passed on the death of Sir Buckston Browne and Mr. Cecil A. Joll. Prof. Ernest Finch of Sheffield was elected a member of the Court of Examiners for a period of three years. The Association of Municipal Specialists was admitted to the joint secretariat under the auspices of the College at 45, Lincoln's Inn Fields. Mr. McAdam Eccles was reappointed a representative of the College on the British Social Hygiene Council for the year 1945. The Council received from Mrs. Braithwaite a portrait by Frank O. Salisbury of the late Leonard Ralph Braithwaite, F.R.C.S., formerly Vice-President of the College.

Diplomas of membership were granted to Diana M. Beyts, R. McK. Laslett, and W. D. G. Tellam, and to the 125 candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London in the *Journal* of Feb. 10 (p. 203).

ROYAL COLLEGE OF PHYSICIANS OF LONDON

B. H. C. Matthews, C.B., ScD., will deliver the Oliver-Sharpey Lectures at the College on Tuesday, March 13, and Thursday, March 15, at 4 p.m. His subjects are "The Effects of High Altitude on Man," and "The Effects of Mechanical Stresses on Man," respectively.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a meeting of the College held on Feb. 6, with the President, Dr. A. Fergus Hewat, in the chair, Dr. W. F. T. Haultain was ntroduced and took his seat as a Fellow of the College, and Dr. D. R. Maitland and Dr. I. Douglas-Wilson were elected Fellows.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At the monthly meeting of the College, held on Feb. 2, Dr. Robert Henry Micks, F.R.C.P.I., was elected King's Professor of Materia Medica and Pharmacy.

The following were admitted Licentiates and Members of the College: J. D. Kennedy, Anne McMahon, W. E. O'C. C. Powell, R. Wilson.

WESTMINSTER HOSPITAL MEDICAL SCHOOL

An examination for two entrance scholarships in anatomy and physiology will be held on March 6 and 7. Applications for further particulars should reach the secretary, Westminster Hospital Medical School, 17, Horseferry Road, S.W.1, not later than Feb. 26.

Medical Notes in Parliament

National Health Service

Dr. SUMMERSKILL inquired on Feb. 1 whether the Minister of Health could make a statement on the implementation of the recommendations contained in the White Paper on the Health Services. Mr. WILLINK said he was engaged in discussion of these proposals with representatives of the medical profession and others concerned, and was not yet in a position o make any statement.

Industrial Dermatitis

Mr. IVOR THOMAS asserted on Feb. 1 that medical referees now described by other names conditions which were formerly diagnosed as industrial dermatitis. He said patients were thus deprived of their rights under the Workmen's Compensation Acts. It was a common practice, he said, to describe as eczema or pustular pompholyx what had formerly been described as ndustrial dermatitis. Mr. HERBERT MORRISON said he was not aware there had been such a change. The statutory definition was "dermatitis produced by dust or liquids." He did not hink there was a widespread feeling that this was "an insurance company ramp." He would look into any case which Mr. Thomas had in mind.

Research on Artificial Limbs

Major BRAITHWAITE asked the Minister of Pensions on Feb. 1 whether he had yet received any recommendations rom the Departmental Committee on Artificial Limbs.

Sir WALTER WOMERSLEY: Yes, Sir. I have received an nterim report which I will circulate with the official report. t recommends: (1) the appointment forthwith of an officer o undertake research and development work; and (2) the seting up of a standing advisory committee. I have accepted both recommendations, and Dr. A. W. J. Craft, whom I have elected for the research post, will shortly take up his new duties.

Medical Care during Sick Leave

Sir GEORGE JEFFREYS asked the Secretary of State for War whether he was aware that wounded officers and other ranks on sick leave were ordered to attend before medical boards at the hospital in which they were treated on their first return o this country, regardless of the distance from their homes or places of residence; and whether he would arrange in future for uch officers and men to attend both for any necessary treatment nd for medical boards at the nearest suitable hospital to the ddress at which they were residing while on sick leave. Sir JAMES GRIGG said that whenever possible medical boards on wounded officers and other ranks returning to this country were held before they were sent on leave, whether it was disembarkation leave, normal privilege leave, or, in the case of officers, sick leave. If at any time, owing to the numbers involved, this was not possible, the rule was that the patient should have his medical board at the hospital to which he was assigned for treatment. This should be as near to his home as possible, except in cases where he required special treatment and must be sent to a hospital with the appropriate facilities. He was aware that in a few cases this procedure had not been properly carried out, and that some men had been returned unnecessarily to the hospital where they were first treated on return to this country. Steps were being taken to prevent this.

Water Bill

The Water Bill, 1945, which was introduced in the House of Commons on Feb. 2, for the first time places on the Minister of Health the statutory duty of providing adequate water supplies and conserving of water resources throughout England and Wales. Among the main proposals of the Bill are the following: The Government's Central Advisory Water Committee is to be reconstituted as a statutory body. Surveys of bulk needs of large areas are to be continued where necessary in England and Wales by Joint Advisory Water Committees The Minister of Health is to have power to call for information and statistics from all water authorities and other users of water. Existing local organization is to be retained, but the Minister's powers of direction and powers in cases of default are to be strengthened; amalgamation of undertakings and joint action are to be encouraged and, if necessary. enforced to secure efficiency and economy. Special steps are to be taken to protect water resources, especially underground ones, against misuse, waste, and pollution. In some instances a licence will be necessary in future before new wells can be made or existing ones enlarged. There will be penalties for pollution of water used for human consumption. Statutory undertakers are to be permitted, subject to proper safeguards. to take water from rivers and streams on reasonable conditions, and to acquire land by agreement or compulsorily. Local authorities are required to see that mains are brought wherever practicable to a suitable point which will enable a house to be connected at a reasonable cost, and that a *piped* supply is brought into the house.

Refresher Courses for Service Doctors

On Feb. 6 Sir E. GRAHAM-LITTLE asked the Minister of Health whether he would include in his scheme to provide refresher courses for serving medical officers, qualified and registered practitioners now serving in His Majesty's Forces not as medical officers. Mr. WILLINK: Yes, Sir.

Medical Officers of Health for Europe

On Feb. 6 Sir H. MORRIS-JONES asked the Minister of Health how many medical officers of health for counties. county boroughs, or urban district councils were at present being enrolled for work in the freed countries of Europe: how many had agreed to take up this work; and what arrangements were being made to look after the public health of this country in view of the present scarcity of medical personnel in civilian life. Mr. WILLINK said that 40 local authorities had been invited to consider the temporary release of medical officers for service with the civil affairs organizations in the liberated countries of Europe. So far 14 authorities had signified their consent. When a medical officer was being seconded in this way, arrangements for carrying on his public health duties in the area concerned were made by reorganization of the authority's medical staff or, in some instances, by transferring or sharing the services of a medical officer of another authority.

Fatal Smallpox Cases in Scotland

On Feb. 6 Mr. LEACH asked the Secretary of State for Scotland whether his Department made any inquiry into the deaths from vaccination or associated with vaccination performed during the smallpox outbreak in 1942; how many of such deaths were eventually discovered; the areas in which they occurred; and where the 10 deaths from vaccination or post-vaccinial encephalitis mentioned in the report on the Edinburgh smallpox outbreak occurred. Mr. JOHNSTON said that medical officers of his Department were in close and constant touch with medical officers of health during the period of this outbreak, and paid special attention to deaths associated with vaccination. During the period 21 such deaths were reported. Of these 10 were in Edinburgh, 5 in Fife, 4 in Glasgow, 1 in Lanarkshire, and 1 in Midlothian. The 10 deaths mentioned in the recently published report by the Edinburgh public health department all occurred in Edinburgh.

War Gratuities

Sir JOHN ANDERSON on Feb. 6 announced that the Government had decided to make provision for war gratuities to Service men and women after the war. The gratuity would depend on length of war service as well as on rank. Regular and ex-regular officers and men were included in the scheme. The basic rate for ratings and other ranks would be 10s. for each complete month of service and for the lowest rank of officer 25s. Women members of the Forces and nursing officers would, in general, receive two-thirds of the rate for corresponding male ranks.

Allocation of Doctors

On Feb. 7 Sir HENRY MORRIS-JONES asked what body or committee determined the priority between the three Services in regard to medical personnel; and whether it had recently had its attention directed to the danger of calling up any further medical men and women from civilian life, especially in rural areas. Mr. WILLINK said the allocation of doctors between the three Services and between those Services and the civil population was determined by the Government with the advice of the Medical Personnel (Priority) Committee presided over, by Sir Geoffrey Shakespeare. This committee, which contains representatives of various branches of the medical profession as well as of the Services, had the subject under continuous review since it was constituted in 1941. The Government was alive to the aspect of the matter referred to in the second part of the question and to other relevant considerations.

Red Cross Visits to Japanese Camps

Mr. RICHARD LAW reported on Feb. 7 that the International Red Cross Committee had communicated a proposal from the Japanese Ministry of Foreign Affairs agreeing under conditions to visits by representatives of the International Red Cross to a prisoner-of-war hospital in Siam and a prisoner-of-war camp at Singapore. This did not cover more than a fraction of the camps in the southern areas, but the Japanese said they regarded it as a first step. The offer was conditional on representatives of the International Red Cross being permitted to visit Japanese subjects held in Allied countries. The British Government had replied that neutral representatives were permitted to visit all Japanese held in the British Empire.

Committee on Handicapped Children

Mr. R. A. BUTLER announced on Feb. 8 that he had appointed the following as an advisory committee on such matters relating to children requiring special educational treatment as he submitted to them or as they considered require investigation: Mr. Frederick Messer, M.P. (chairman), Prof. J. M. Mackintosh, Dr. A. A. E. Newth, and Mr. E. W. Woodhead (Director of Education, Kent). Mr. Butler added that to assist the committee in their consideration of any specific question under review he would from time to time appoint as additional members persons possessing special knowledge and experience of the particular category of handicapped children concerned.

Prevention and Treatment of Blindness

Mr. BEATTIE inquired on Feb. 8 whether the Secretary of State for Scotland had in view any extension of facilities for the prevention and treatment of blindness among the civilian population by amendment of the Prevention and Treatment of Blindness (Scotland) Act, 1938, or otherwise. Mr. JOHNSTON replied that provision for prevention and treatment of blindness had hitherto been made by Scottish local authorities, in varying measures, as part of their maternity and child welfare, school health, tuberculosis, and other services. A few authorities exercised their powers under the Act of 1938 to extend such provision to persons outside the scope of these special services. In certain areas also voluntary hospitals provided valuable facilities, and voluntary societies for the blind had done most useful work. As part of the National Health Service, it was contemplated that every person would have access, either through his general practitioner or through an appropriate local clinic service or otherwise, to all necessary specialist and hospital facilities required for all purposes, including those for the prevention and treatment of blindness.

Veterinary Education

Mr. R. S. HUDSON, replying on Feb. 8 to Col. Ropner, said improvement of veterinary education was regarded by the Government as a matter of national concern. A committee under the chairmanship of Dr. Loveday appointed by Mr. Johnston and himself had made recommendations for the improvement of veterinary education. These were unde consideration by the Government and the various bodies concerned. The Government's financial contributions to medica and veterinary education were on different bases. Grant made to the two veterinary schools in England during the las four years amount to nearly £100,000. The Loveday Committee's recommendations envisaged substantially larger grant for the veterinary educational facilities they proposed. Th Government did not contribute financially to the Veterinar Educational Trust, which was intended to supplement othe resources.

Certificates of Incapacity

Mr. BEVIN on Feb. 8 said he had no power to prohibi employers from asking for medical certificates in support o absence. Special arrangements had been agreed with employers organizations, trade unions, and the medical profession whereb a certificate in standard form could be obtained for 1s Mr. TOM BROWN asserted that some employers, beside demanding the certificate, asked that the first bottle of medicine shoul be taken at the works after it had been received from th doctor. Dr. SUMMERSKILL asked why employers did not recognize National Health Insurance certificates as evidence of capacity. Mr. BEVIN replied that in some cases these certificate were not conclusive evidence.

Health in the Army.—On Jan. 30 Mr. VIANT asked the Secretar of State for War whether he was aware that a report on the healt of the armed Services had been published in America, in whic information on the amount of sickness in the American Army i 1942 and part of 1943 was given, based on official information and whether his Department was in possession of statistics relatin to disease in the Army in every theatre of war. Sir JAMES GRIG said that he had not yet seen a copy of the report referred to. Th answer to the second part of the question was in the affirmative Owing to the shortage of staff it was unlikely that statistics abou the health of the Army would be published until the war was ove

Accidents in Mines.—On Jan. 30 Major LLOYD GEORGE, replyin to Mr. Bowles, said that 4,363 persons were killed at mines an 15,240 seriously injured from the beginning of the war to the en of 1944. Figures of minor injuries were not available for period shorter than a year. During the five years ended December, 1943, th latest period for which figures were available, the total number o injuries involving absences from work of more than three day was 779,260. The number of fatal accidents last year was the lowes on record.

Calcium in Bread.—Col. LLEWELLIN, in reply on Jan. 31 t Mr. Martin, said calcium was the only extraneous ingredien included generally in the national loaf to-day, which was not presen in the pre-war loaf. As substantial advantages had been obtaine from this addition he was not prepared to make available an alternative national loaf without it. Specialty breads containing no adde calcium were available from most bakers.

Nutrition and Health of Miners.—Mr. ATTLEE told Col. Ropne on Feb. 1 that clinical and scientific inquiries into the health an nutritional state of miners had been and would continue to be made He was taking up with the interested Departments the questio whether a more general survey would be helpful, and if so by wha agency it could best be conducted.

Notes in Brief

No change is contemplated in the present priority arrangement for milk so long as the consumption of milk by the general publi has to be restricted. Col. Llewellin states the latest returns sho that hospitals are getting more milk than they ever had before.

Exact figures for the incidence of hernia in the mining industr are not available, but only 1% of the miners applying to leave th industry on medical grounds advance hernia as the cause of disability.

Hospitals and institutions already have the highest priority fo such nursing staff as they require urgently. During the nine month ended Sept. 30 the net increase in the number of nursing sta employed in hospitals and institutions was approximately 3,500, o which about 600 were part-time nurses.

Despite several approaches the Japanese Government has show itself completely uninterested in exchanges of prisoners of war an has refused even to contemplate an exchange of sick and wounded A small batch of telegrams from British prisoners of war in the Fa East have been received recently. These are the first such telegram to reach this country.

Forty-three claims for pensions made by widows of members o the Forces who have died of cancer have been allowed by Pension Appeals Tribunals and 465 refused.

Seventeen Pensions Appeals Tribunals have been established. I the hearing of cases by them preference is given to the severel disabled.

There were 201 outbreaks of foot-and-mouth disease during th 12 months ended Feb. 1. Ninety-two were due to spread of infec tion from other animals. In 95 of the remaining outbreaks th disease first appeared among pigs, and in 23 the animals were owne by butchers.

Medical News

Technical fuel experts and members of local authorities will attend joint conference of the Institute of Fuel and the National Smoke batement Society in London on Feb. 23. The conference will be pened by Major Gwilym Lloyd George, M.P., Minister of Fuel nd Power.

The next meeting of the Association for Scientific Photography be held on Saturday, Feb. 24, at 2.30 p.m. in Caxton Hall, estminster, will be devoted to spectrography.

The Duchess of Kent, president of the National Association for e Prevention of Tuberculosis, has promised to attend a meeting sanatorium matrons to be held in B.M.A. House on Thursday, larch 1, at 3 p.m., when a Matrons' Section of the N.A.P.T. will formed.

The Galton Lecture of the Eugenics Society, on "Eugenics in etrospect and Prospect," will be delivered by Dr. C. P. Blacker -day (Friday, Feb. 16) at 4.30 p.m., at 26, Portland Place, W. The cture is open only to fellows and members and their guests.

The programme of medical films arranged by the Scientific Film ssociation will be shown at the Royal Society of Medicine , Wimpole Street, W.) on the fourth Wednesday in February, larch, April, and May (*not* the fourth Thursday as previously nnounced). Each programme will be given at 5.30 p.m. and again t 8 p.m. and will consist of examples of a general interest introuction, a specialized illustration, a direct teaching film, and, lastly, broad discussion of a subject. Application for admission should be ade to the hon. secretary of the medical committee of the association, Dr. S. J. Reynolds, at 14, Hopton Road, London, S.W.16.

Doctors who have professional premises in another district from at in which they live are entitled to a professional vote for those remises. This applies with particular force in London to doctors ith professional premises in the Marylebone parliamentary division. hey should note, however, that under the new Registration of the eople Act they will not be entitled to such a vote unless they first omplete the necessary form, which can be obtained from their town all or local council's office, and return it to the Local Electoral egistration Officer of their district before Feb. 28 next—that is, ithin ten days' time. Doctors who fail to do this will be unable record their professional vote at the general election. It should so be noted that the husband or wife of an occupier of professional premises is no longer eligible for the vote for those premises.

EPIDEMIOLOGICAL NOTES

Discussion of Table

England and Wales during the week whooping-cough fell incidence by 160 cases, diphtheria by 68, dysentery by 82, d scarlet fever by 54; measles notifications rose by 887.

Only one case of diphtheria was reported from Caernarvonire, Bangor M.B., where there were 55 cases in the outbreak st week. In Lancashire cases of diphtheria rose by 20. The wer incidence of whooping-cough was due mainly to the crease in the south-west and south midlands; elsewhere there as little change. Scarlet fever notifications in Lancashire ll by 52. Notifications of measles were higher than last eek by the following figures: Yorks West Riding 378, orcestershire 199, Middlesex 157, Lincolnshire 128, Staffordire 122, London 91; in Lancashire the incidence fell by 5, in Durham by 111, and in Nottinghamshire by 75.

There were 59 more cases of dysentery in the outbreak in uckinghamshire, Aylesbury R.D., where 62 cases were reported st week. Only 19 cases were notified in Yorks West Riding, mpared with 92 and 100 in the two previous weeks. The her large centres of infection were Essex 23, Gloucestershire , London 20, Lancashire 20, Suffolk 19, Middlesex 15, Kent , Derbyshire 13, Surrey 10, Northumberland 10.

In *Scotland* notifications of infectious diseases fell by the llowing figures: whooping-cough 75, scarlet fever 63, acute imary pneumonia 42, measles 18; notifications of diphtheria se by 18, and of dysentery by 4. In Edinburgh cases of sentery rose from 8 to 23.

In *Eire* the incidence of infectious diseases underwent little ange during the week. Diphtheria is still widespread, the cases involving forty-three registration areas.

In *Northern Ireland* the measles incidence continued to fall, ere being 160 notifications, compared with 281 three weeks rlier.

Week Ending February 3

The notifications of infectious diseases in England and Wales ring the week included: scarlet fever 1,401, whooping-cough 02, diphtheria 415, measles 16,039, acute pneumonia 1,366, rebrospinal fever 76, dysentery 376, paratyphoid 2, typhoid 4. eaths attributed to influenza in the great towns numbered 89.

No. 4

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 27.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths; and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

Annual rate per 1,000 persons living			16·3	16·6	§			18·1	26·8	§
Stillbirths	198	18	27			220	25	35		
Rate per 1,000 total births (including stillborn)			32					38		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.) TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Calamine Lotion

Q.—*Calamine is impure zinc oxide. Have the impurities any merit apart from the cosmetic effect of the pink colour? What is the pigment? Why is calamine mixed with equal parts of pure zinc oxide in many formulae?*

A.—Calamine may or may not contain zinc oxide, being chiefly zinc carbonate to which a small amount of iron oxide is added for its cosmetic effect. Its addition to the calamine lotion is therefore partly as a colouring matter and partly to produce a suitable concentration of a zinc salt.

Acquired Immunity

Q.—*Where an acquired immunity is life-long, do the same molecules of antibody remain in the blood indefinitely? If not, what is the stimulus to the formation of new ones?*

A.—Antibodies, once formed as globulin, do not persist for long in the circulation, as is shown by the temporary immunity of a few weeks' duration conferred on a child who is passively protected with homologous convalescent measles serum, or by the infant who remains resistant to the common childhood fevers during the first few months of life, presumably because of the passive transfer of antibody from the mother via the placenta. Where immunity is actively acquired and lasting, as happens with many bacterial and virus infections, it does not necessarily follow that there is demonstrable antibody in the patient's blood. However, in yellow fever, and probably also in measles, the life-long immunity is associated with circulating antibody, and no one has yet given a satisfactory explanation of this phenomenon. There are two views: either the antigen persists in or on the antibody-forming cells, presumably the reticulo-endothelial system, for many years acting as a sort of template; or these cells, once having received the imprint of a particular antigen, go on producing specific antibodies and pass on this property to their descendants, even in the absence of antigenic stimulus. Persistence of the infectious agent is known to occur in trypanosomiasis, rickettsial infections, and herpes labialis, but there is no epidemiological evidence for its occurrence in yellow fever or measles or typhoid. Thus there seems no escape from the view that life-long immunity depends on some property acquired and transmitted by the antibody-producing cells in the absence of any antigenic stimulus. The interested reader should read the excellent review, *Production of Antibodies,* by F. M. Burnet and others (London, 1941).

Haemin and Anaemia

Q.—*During a discussion it was suggested that haemin might be used in the treatment of microcytic hypochromic anaemia. We were unable to adduce any theoretical evidence against such a form of treatment, but would be grateful if you would consider our reasoning* [*omitted here*] *and point out flaws in it.*

A.—The scheme for the synthesis of haemin has certain weaknesses. Although the ionic form in which iron is absorbed from the intestine is still a matter under investigation, it would seem from existing evidence that it is absorbed chiefly in the ferrous state. In fact metabolic reactions within the stomach tend to maintain iron in this condition. Whether iron compounds can react with haematin or protoporphyrin in the plasma is doubtful. Neither haematin nor protoporphyrin has been detected in normal plasma; small amounts of protoporphyrin have been found in reticulocytes. It is difficult to visualize a mechanism whereby a reaction between haematin (or haemin) and globin, taking place in the plasma, would lead to haemoglobin. Globin is not a normal constituent of plasma, and haematin in plasma would probably form methaemalbumin (ferriprotoporphyrin albumin). The reaction between haemin and globin suggested in the question would not lead to a naturally occurring iron-porphyrin-globin pigment. Haematin in combination with globin gives methaemoglobin (ferriprotoporphyrin globin whereas haem gives haemoglobin (ferroprotoporphyrin). In bot these compounds the valency bonds of the iron atom have bee shown, from measurements of their magnetic susceptibility, to b essentially in the ionic condition; in haemoglobin Fe^{++}, an methaemoglobin Fe^{+++}. In oxyhaemoglobin the bonds are essen tially covalent and the iron atom is linked to the pyrrole nuclei i a manner similar to that in the formula in question.

Haemin would not be an effective substitute for iron salts in th treatment of microcytic anaemia. Given orally, haemin suffers th same fate as the haem of haemoglobin in the intestine. It is decom posed into protoporphyrin and iron. The intravenous administra tion of haemin would be difficult, since haemin is not soluble i solvents at a *p*H near to that of blood. The best solvent for haemi is sodium hydroxide, and the use of alkaline solutions of *p*H 8 or is clearly not to be recommended for intravenous administration.

Sulphanilamide per Rectum

Q.—*How should sulphanilamide be given per rectum? In th M.R.C. Memorandum on the medical use of the sulphonamide page 15, there are directions for giving sulphanilamide per rectu which beat even the brain of a mathematical friend. According our deductions, one could not give a satisfactory dose by this metho I would be glad if you could throw some light on the subject.*

A.—Why should the questioner and his friend be so baffled b these simple directions? They are that a saturated solution c sulphanilamide (0.8%) be prepared, of which "the required quantit is brought up to a total volume of 300 c.cm., if necessary, by admix ture with 1% glucose in normal saline. . . ." If no such additio were considered "necessary" the dose would be 2.4 g.—given fou hourly, is this not a "satisfactory dose"? This method of adminis tration is nevertheless not to be recommended, owing to slow an sometimes incomplete absorption; it should rarely be necessary.

Common Salt for Cleaning Teeth

Q.—*A school has instituted the practice of cleaning teeth wit common salt instead of toothpaste. Has this any advantages o disadvantages?*

A.—Common salt is excellent for cleaning teeth and has been i use for generations for this purpose. It has the great advantage c being cheap and in plentiful supply, but the taste is an acquired on and many people do not like it. It matters little what dentifrice i used so long as the teeth and gum margins are brushed conscien tiously at least twice daily, and common salt (or common soap) as good as, if not better than, the proprietary articles, though it ma not be as pleasant or attractive. It is encouraging to hear of school insisting on a routine of this nature, for the dental health c the grown man depends very largely on the habits acquired in h youth.

Estimating Antibodies

Q.—*What is the technique for estimating antibodies, specific an non-specific?*

A.—There is a variety of methods for testing for the presence c specific antibodies. The best-known is the agglutination reactio which occurs as bacterial clumping and sedimentation when suspension of the micro-organism suspected of causing the infectio is mixed with suitable dilutions of the serum of the infected patien Antibodies may take a week or more to appear after onset of th clinical infection, so that, in typhoid fever, for example, the Wid test, which is an agglutination reaction, will give no positive informa tion before 7 to 10 days. Another common method of estimatir antibody is the complement-fixation test, of which the Wasserman reaction is an example. Or antibody may be demonstrated by precipitation reaction, or the animal protection test, or oth specialized techniques suitable for particular infections. Details c the usual methods for estimating antibodies are to be found in an bacteriological textbook, but these tests should not be undertake by persons who have not had a laboratory training.

What does the questioner mean by non-specific antibody?

Treatment of Ascariasis

Q.—*Roundworms are extremely common in this area (Bomba Presidency). Santonin has to be given very frequently. Under th existing sanitary conditions, formation of roundworms cannot b prevented. What is the safe dose for repeated administration?*

A.—In adequate dosage santonin is always liable to cause tox manifestations, sometimes very severe; there is therefore no sa *effective* dose. Oil of chenopodium is rather more efficient, but als is toxic. A good method of treating ascariasis in adults, which i the area mentioned is likely to be associated with hookworm infesta tion, is to give ol. chenopodii 0.3 c.cm. with tetrachlorethylen 2.7 c.cm., followed in an hour or so by a sharp saline purge. Th treatment may be given, with adequate spacing, several times a yea

Oculogyric Crises in Encephalitis Lethargica

Q.—*Is there any effective method of controlling the severity and equency of the oculogyric crises which are such a distressing ymptom of chronic encephalitis lethargica?*

A.—Oculogyric crises sometimes respond well to the ordinary eatment of encephalitic Parkinsonism; for example, tincture of ramonium pushed to the limit of tolerance or a mixture such as ıe following:

℞ Hyosc hydrobrom.	gr. 1/200
Tinct. stramon.	♏ 15
Tinct. bellad.	♏ 10
Sod. brom.	gr. 10
Aq.	ad oz. 1/2

Sig.: 1/2 oz. t.d.s.

Amphetamine sulphate in doses of 5 mg. three times a day and) mg. at the onset of an attack may also help. Artificial pyrexia ıight be tried for a patient who responds to nothing else. In some ıses, unfortunately, the spasms recur in spite of all treatment.

Estimating Osmotic Pressure

Q.—*Would you describe the most delicate method of noting ıanges in osmotic pressure, or tell me where a description can be ound?*

A.—Direct methods for estimating osmotic pressure are laborious ıd difficult, requiring a well-equipped laboratory. Estimation of ıpour pressure and depression of freezing-point are the chief ıdirect methods. Chapter 41 in J. Reilly and W. N. Rae's *Physico-hemical Methods,* 1933, published by Methuen (London), or .. Findlay's *Osmotic Pressure,* 1919, published by Longmans ondon) will be helpful.

Case of Peritoneal and Pleural Effusion

Q.—*A man aged 29, with no past illnesses, on June 1, 1944, had ffuse abdominal pain and pain on micturition. He went to ormandy on "D" day, but 15 days later had to be sent home with greatly distended abdomen. A large amount of yellow fluid with fibrin deposit was removed: protein, 600 mg. per 100 c.cm.; no ganisms. Later he developed small bilateral pleural effusions, hich soon absorbed. Ascites and pleural effusions have not curred. He feels well except for a dragging pain on standing. e is apyrexial, and sedimentation rate is 14 mm. in one hour. ıggestions as to the probable diagnosis will be welcomed.*

A.—It is difficult to offer a satisfactory diagnosis. The presence fibrin suggests an inflammatory exudate. Possibilities are a non-ıppurative acute peritonitis due to a leaking perforation, or less obably a pneumococcal or streptococcal infection. On the other ınd, the low protein content of the effusion suggests a transudate. ıis might be due either to a constrictive pericarditis—the most tisfactory explanation of the simultaneous involvement of the eura—or, less probably, a thrombosis of the portal vein. If con-ictive pericarditis is present, the heart may appear normal but e venous pressure should be high. It would be appropriate to amine by *x* rays the heart and pericardium; the lower oesophagus r varices; and the stomach and duodenum for ulcer. If these aminations are negative, the function of the liver should be ıdied.

Urinary Antisepsis

Q.—*At a recent discussion on pyelitis it was stated that in the sulpha" treatment the urinary concentration of the drug was of eater importance than that in the blood; consequently smaller ıses were advised. Upon what evidence is this opinion based? there reliable statistical evidence to show that recurrences are eater or less after adequate treatment with sulphonamide, as com-red with the alkaline treatment alone?*

A.—This is not an opinion; it is a fact that the action of any ınary antiseptic depends on its concentration in the urine. If this ıre not so, there would be no urinary antiseptics except the lphonamides and penicillin, since no others have any action in e blood and tissues. The urinary concentrations of the several lphonamides required to inhibit the growth of the various bacteria mmonly causing urinary-tract infections have been determined appropriate *in vitro* methods by H. F. Helmholz (see, for stance, *Proc. Mayo Clin.,* 1940, **15,** 651, for his data on sulpha-azole), and concentrations well in excess of those necessary for ppressing the more susceptible bacteria can be attained on very ıderate dosage.

We know of no statistics of the frequency of recurrence after ferent forms of treatment. The main difference between sulphon-ıide and alkaline treatment is that the former will cure a large ıjority of suitable cases in a week, whereas the latter leaves the re to Nature.

*** Helmholz's article was commented on in an annotation in the *M.J.* of April 5, 1941 (p. 521). Previous comments on his work urinary infections appeared in the *B.M.J.,* 1937, **1,** 396; 1937, **2,**); 1938, **1,** 459.

Sodium Cacodylate

Q.—*Is sodium cacodylate of any use in the treatment of chilblains, and if so in what dosage should it be prescribed?*

A.—The cacodylates were introduced some fifty years ago as almost a specific remedy for certain conditions, such as tuberculosis, pernicious anaemia, and leukaemia. Sodium cacodylate contains about 62% of arsenious acid; it has proved an entirely disappointing remedy and is not recommended in the treatment of chilblains.

Iodine as Contraceptive

Q.—*I have heard that in Russia a common method of contraception is the painting or swabbing of the cervix with tinct. iodi mitis immediately after each period, thus avoiding the use of pessaries, etc. Is this so, and what are the advantages and disadvantages of the method?*

A.—The method in question involves the introduction of iodine *into the uterine cavity,* rather than its application to the cervix. The object is to damage the endometrial surface to such an extent that the implantation of a fertilized ovum is either prevented, or is so disturbed that an early abortion results. It has been employed mostly in Russia and Germany. A 10% solution of iodine, or a mixture of equal parts of tincture of iodine (?, fortis) and glycerin, is used, and is carried to the uterine cavity by cotton-wool mounted on a probe. The cervix may need to be dilated first. As a rule, the treatment is carried out once a month, before or after menstruation. A modification of this method is to *inject* a small amount of iodine solution into the uterus, and it would appear that this technique is employed not only to prevent implantation, but to induce abortion of an already established pregnancy.

The repeated introduction of irritant chemicals into the uterus in this way is to be condemned. If it is to be effective, there must be injury to the epithelium, and this in turn may be followed by infection. Moreover, the infection may not be limited to the uterus, and cases of pelvic cellulitis and acute salpingitis are recorded—although in some of these cases it may be that the woman was already pregnant before treatment. Permanent sterility might result, and it has been suggested that there is increased likelihood of ectopic pregnancy. The actual introduction of the iodine solution causes uterine spasm, and is painful; vomiting and collapse may occur. Not only is this method of contraception (or rather induction of abortion) dangerous, but it is unreliable, and there is little if anything to be said in its favour. The details of the technique are described by E. J. Kvater in *Contraceptive Methods and their Technique* (1926), and the method is discussed by C. A. Selitzky, chief of the gynaecological department of the Moscow State Hospital, in *Contraceptive Methods in the Light of Modern Science* (1929). The latter concludes that the use of such methods is unjustifiable. These pamphlets are published by the State Department of Health in Moscow, and both are referred to by Antoinette F. Konikow in her book, *Physicians' Manual of Birth Control* (1931), page 114.

Flexor Spasms in Octogenarian Tabetic

Q.—*An octogenarian tabetic, otherwise healthy, suffers from spasticity of his right leg. When he tries to sleep and conscious control is relaxed, his right leg assumes a position of extreme flexion at both hip and knee. He is able to sleep only in this uncomfortable posture, with the right thigh pressed close to the abdomen and his heel almost touching his buttock. Sedative drugs (short of morphine, which has not been used) have no effect. No splint or other restrictive device can be tolerated. Is there any medical or surgical procedure likely to give relief?*

A.—Spasticity is not part of the clinical picture of tabes, so that in this case there must be an associated lesion of the pyramidal tract, presumably syphilitic. Flexor spasms such as those described are a feature of paraplegia in flexion, though rarely confined to one lower limb. If sedation is ineffective the only possible treatment would be an extensive division of the posterior roots from the lower dorsal level downwards on the affected side, to interrupt the reflex arc, but such a serious operation would be out of the question in an octogenarian.

Sudanophobic Units

Q.—*In the* JOURNAL *of Aug. 12, 1944 (p. 212), there is an article by Hemphill and Reiss which mentions "sudanophobic units" of "corticotrophic hormone." Sudanophobic units are quite new to me, and I should appreciate information about them.*

A.—This method of standardization of corticotrophic hormone is based on the ability of the hormone under test to produce regeneration in the sudanophobic zone of the adrenals of the rat after hypophysectomy. It is fully described by M. Reiss, J. Balint, and F. Oestricher (*Endokrinologie,* 1936, **18,** 1). The method was "rediscovered" and has been described by H. M. Evans and Choh Hao Li (*Endocrinology,* 1943, **33,** 261).

INCOME TAX

Amount of Tax Payable

"Colony" inquires what tax he would have to pay in this country on the income shown below, assuming the continuance of present allowances and rates of tax.

⁂ The income-tax year ends on April 5: If "Colony" comes to this country on, say, December 5, 1945, the position for the first two years or so will be approximately as follows:

(*a*) 4 months to April 5, 1946—tax payable, say £45.
(*b*) Year to April 5, 1947—

	£	£
Earned income:		
8 months to Dec. 5, 1946 = 2/3 of £1,100	733	
4 „ „ April 5, 1947 = 1/3 of £500	167	
		900
Allowances, 1/10 of £900	90	
Married allowance	140	
"Children" allowance	100	
		330
		570

		£	s.	d.
£165 at 6s. 6d. ..		53	12	6
£405 at 10s.		202	10	0
£570	Total tax	256	2	6

(*c*) Year to April 5, 1948:

	£	£
Earned income	500	
Investment income	39	
		539
Allowances:		
Earned income 1/10 of £500	50	
Married allowance	140	
"Children" allowance	100	
		290
		249

		£	s.	d.
£165 at 6s. 6d. ..		53	12	6
£84 at 10s.		42	0	0
£249	Total tax	£95	12	6

Post-war credit would be due—i.e., (*a*) £18, (*b*) £50, and (*c*) £36. The lump-sum payment arising from partial conversion of the pension is not taxable, but any income arising from the investment of it would, of course, be taxable. It has been assumed that "Colony" can establish the fact that some War Bonds standing in his name are held by him in trust for his sons, and that the interest thereon is therefore not liable to tax as being his income.

LETTERS, NOTES, ETC.

"Structural" instead of "Organic"

Dr. P. E. **Dipple** (Sawbridgeworth, Herts) writes: It has occurred to me for some time that a point in the accepted cataloguing of diseases needs revision. I refer to the main division of all diseases into the groups of either organic or functional. If we are to retain the term "organic" then surely functional diseases should be termed "inorganic." May I suggest that what we now refer to as organic should be entitled "structural" diseases, this term implying some change of structure, either macroscopical or microscopical, or both, and the term "functional" to be retained in its present usage to label those diseases where no structural changes can, *at present*, be demonstrated. Such a nomenclature would appear to me to be more logical than that now in use. Surely functional diseases are also organic inasmuch as the function of one or more *organs* is involved.

Demobilization and the E.M.S.

"1939 **Volunteer**" writes: I am greatly surprised at the sense of grievance evident in the letter under this heading in your issue of Oct. 7 (p. 482) just to hand. I think that if your correspondent will answer honestly the following questions he will probably realize that neither he nor his fellow members of the E.M.S. have any legitimate grievance. (1) What does he mean by "virtual" conscription? (2) Did he volunteer for service with the armed Forces before his "conscription" into the E.M.S.? If he did not do so, and had to be conscribed into the E.M.S., what work did he propose doing during the war? (3) What disadvantages (domestic, educational, or financial) has he suffered by being a member of the E.M.S.? Has he gained any advantages in these respects over his contemporaries serving in the armed Forces? While the proposed scheme of demobilization of the armed Forces depends on age and length of service it should be realized that this is only so that thereby the scheme becomes workable; but morally, factors less tangible and not so easily measured are of more importance—viz., hardship suffered and sacrifices made. No one will deny how great has been the amount of useful work done by the E.M.S., but surely it cannot be claimed that this has involved serious hardship on its members. In conclusion I would like to suggest that if there should be any difficulty in releasing medical officers from the armed Forces before members of the E.M.S. are released, then members of the E.M.S. (provided they are under the age of, say, 40) should be conscribed to replace those in the armed Forces. In this way it may be possible to mitigate the disadvantages (especially educationa which will otherwise face the Service medical officer in the inevitab post-war scramble for a livelihood.

Rocking Movements in Sleep

A. B. C. writes: With regard to the question on this subject i the *Journal* of Dec. 2, 1944 (p. 744), and the letter appearing in th issue of Dec. 23 (p. 842), it may interest your correspondents if cite the case of my younger daughter. She is now 12½ and abo the average in intelligence, and she has always been a good sleepe like the rest of her family. From the age of about 3 months un quite recently she has been in the habit of vigorously rocking herse to sleep, both when first settling down for the night and aga whenever sleep became light for any reason. When this occurs s is usually lying on her back, never on her face, often with her han behind her head so that her projecting elbows act as a sort oscillating fly-wheel, causing her head and shoulders to ro violently from one side to the other. When she was quite sma the violence of this rocking shook the cot or bed, causing it creak, and thereby disturbing others, but now that she is older t rocking is less frequent and much less violent. She is trying overcome the habit, and has, I think, practically succeeded, but the rocking occurs only when already asleep, she has found difficult to exercise conscious control over it. She is now at boarding school, and only once recently has her rocking disturb the other girls. I have not seen or heard it myself for some tin now. There is no familial history of rocking, and her elder sist never did it. She was never rocked in her cradle by a nurse duri infancy, but she seemed to discover the advantages of rocking f herself. She seems to have a well-balanced personality and to normal both physically and mentally. Personally I do not rega the habit as in any way pathological—rather, perhaps, as a man festation of a somewhat original and independent spirit! But used to be a terrible nuisance!

Aetiology of Erythema Nodosum

Dr. Eva **McCall** (Sunninghill, Berks) writes: I have read wi much interest Prof. Bruce Perry's paper (Dec. 30, p. 843), for to n it has a personal application, which, in my case at least, seems point to a rheumatic origin of this condition. When I was a scho girl I had an attack of erythema nodosum, and can still rec after all these years the red nodules over the tibiae, accompani by acute pain and tenderness in the legs and inability to walk. Th point I wish to emphasize is that I inherited the rheumatic diathes my mother having had an attack of rheumatic fever as a you woman, with a resulting endocarditis. I myself am a rheuma subject, and have suffered for many years from the different ma festations of rheumatism, fibrositis, neuritis, and arthritis. In r case there is no evidence whatever of tuberculous infection.

Passive Hyperventilation

Dr. S. **Conchubhair** (Dublin) writes: The inquiry of B. (Dec. 30, p. 876) reminded me of a method I learnt from the la Dr. P. J. Keogh of Dublin of using passive hyperventilation f the same (or a similar) purpose. When about to induce gene anaesthesia with Clover's inhaler the ether container is filled a the rebreathing bag attached. The facepiece is then applied a the patient told to breathe in and out steadily and strongly. With a couple of minutes the respiration deepens and becomes somewh stertorous, and the patient then becomes drowsy. When depth respiration and duration of hyperventilation are judged sufficie the air valve is rotated fairly rapidly, to "3/4" at once, and then more slowly to "full." The patient then very rapidly becon sufficiently anaesthetized for such procedures as tonsillecton Almost never is there any coughing after the ether is turned and breath-holding is impossible. The quantity of ether used considerably smaller than with the more usual method of inducti On being questioned later patients do not remember having notic any of the unpleasant sensations usually experienced when getti ether. I do not know whether this method is widely kno or has been published, but I send it to you in the hope that, if has not, you may be able to give it a little space.

Recurrent Phlebitis

Dr. A. J. **Colby Tingey** (Epsom) writes: Recurrent phleb (*Journal*, Feb. 3, p. 171) of the infective type is sometimes a sequel fungus infection of the toes. Virulent streptococci may enter the bo through the fissures in the interdigital spaces met with in this con tion. Although the questioner mentioned that the phlebitis was c fined to the veins of the lower limbs in the case referred to, writer of the reply, giving a list of possible infective foci, did suggest that the toes should be inspected. Unless this point recei attention the patient might be subjected to extraction of tee exploration of the nasal sinuses, appendicectomy, cholecystecton and prostatectomy without deriving any benefit. I have had p sonal experience of this form of phlebitis, which incapacitated for weeks at a time.

THE HUNTERIAN MUSEUM: YESTERDAY AND TO-MORROW*

BY

G. GREY TURNER, LL.D., D.Ch., M.S., F.R.C.S.

Hunter will stand out for all time not only as a famous urgeon-pathologist but as one of the first of the great exponents of the experimental method in medicine. The circumstances of the times imperatively dictate that attention should be paid o the story of the other great record which he left to posterity n his collections. This task coincides with my own inclinations, or I have been attracted to museums from my earliest days, and indeed it seems as if the desire to collect had come so naturally as to be almost inborn. There are some who question he value of medical museums or consider that they have become superseded now that the art of book illustration has been carried to such a high state of perfection. Before we go on to consider the huge task of restoring our museum his point of view requires some consideration, for to those of us who so much appreciate museum collections it seems unnatural. When contrasted with even the most precise and beautiful picture the actual specimens seem so much more real: heir size, contour, and perspective are so different from anyhing shown on a flat surface. But the great advantage is that hey can be handled, looked at from all aspects and from new ngles. Further, it is possible to re-examine them by dissection, o cut them up if necessary, and to review their minute tructure by histological methods.

How Hunter was Inspired to Collect

John Hunter's teachers doubtless had their own preparations, nd although I can find no account of Cheselden's collection here seems no reason to think that he would be behindhand. Bart's, always to the fore among the medical schools, is ortunate in that its history has been so carefully compiled y Norman Moore, and in his great work appears the ollowing record by the Governors of St. Bartholomew's Hospital under date of June 23, 1726: "Two convenient rooms were prepared under the cutting ward—one for the more ecent laying of the dead patients before their burial, the ther as a repository for anatomical or chirurgical preparaons." This repository would later contain the treasures of ercivall Pott, and a specimen of a congenital hernial sac with the original roll of paper which Pott placed through he neck not only survives but is still used for teaching nearly 00 years after it was prepared. But undoubtedly the chief imulus was William Hunter's collection, which was well arted before John made that notable journey from Scotland o join his brother as assistant in the dissecting-room. William Hunter in his lecture syllabus always set great store n his preparations, and in it referred to the making of these nd undertook to teach the processes in his anatomy course.

Before we go further into the circumstances which inspired ohn Hunter to build his museum we ought to know something f his fascinating life story. It is with his boyhood that I want specially to deal, for his early years were said to have been asted in idleness, and it was constantly held against him hat at 17 he could neither read nor write and that part of his youth was spent in a carpenter's shop. In after-life John poke of those early years spent in the country around his ome as of special value in cultivating his powers of observaon. In retrospect I think we must recognize that the time spent in close touch with nature was probably among the most valuable in the whole of his life. Like most small boys, Hunter was inquisitive and was always wanting to know the reason for the things he saw about him. Doubtless he had much time to wander about and make observations and to think, but I cannot believe that he was entirely idle. In Scotland in those days there were few who could be, for it was essential that everyone should work for his daily bread. The family was in straitened circumstances, and we may be sure that John not only helped his mother but was employed about the business of their holding. The life of the farmyard must have been thought-provoking, from the traditional query, Why does water run off the duck's back? to Why do fowls sometimes eat their feathers and sows devour their young? Pigeon-lofts infected with contagious tumours, crop-bound fowls, lambs with grass-ill, and "sturdy" sheep, all provide fascinating problems. The accidents to which stock are liable would arouse keen interest in the surgery of injuries and repair, and would certainly teach a reverence for the healing powers of nature. The vagaries of swallowed foreign bodies, like the fate of a needle and thread swallowed by a kitten and discharged from an abscess in the neck when death seemed inevitable, would also be an arresting experience. What lad could ever forget seeing a young horse trailing its intestine on the grass after castration, and what inquiries might it stimulate in after-years in connexion with the anatomy of congenital hernia? Quite possibly the more thoughtful men about the place cut up dead animals in the hope of finding the answers to some of these questions, and thus Hunter would learn the wonders of the disclosures of post-mortem examinations. Life about small farms runs close to nature, and household gossip would often be intimate. The phenomena of reproduction and abortion and obstetric emergencies of all sorts obtrude themselves wherever stock-breeding is part of a hard-won livelihood, and it is interesting to recall that in later life Hunter envisaged artificial insemination. Family illness and episodes of the crises of human fate would often be discussed, and in the Hunter household death was all too familiar. At about 18 it was felt that something should be done to help him to make a career, and he went to Glasgow to assist in the workshop of his brother-in-law, a cabinet-maker. There is no record of how John's time was actually employed, but he probably learnt many lessons not only in using his hands but in conduct, and it would probably be obvious to him that application and industry are the only roads to success. After two years his brother-in-law failed in business and John returned to the old home. Some who have commented on Hunter's later career have rather looked askance at this period in the cabinet-maker's shop and have suggested that he might have been better employed. With this I would join issue, for I believe that a period working with tools, and especially the clean precise tools that wood-workers employ, is an excellent education for anyone destined to use his hands for his life's work.

One of my earliest teachers and colleagues, the late W. G. Richardson of Newcastle-upon-Tyne, was an amateur cabinet-maker who could turn out wonderful work. But with his big clever hands Richardson was also an expert dissector after the true Hunterian style, and some of his preparations were very beautiful. He had the further gift of being able to convey what he saw to paper, and many of the drawings which illustrate his essay on the prostate could scarcely be bettered. Withal he was an expert surgeon, and I have never seen anyone who could carry out a better radical breast operation.

---

* Some extracts from the Hunterian Oration, delivered at the oyal College of Surgeons on Feb. 14, 1945.

When John returned home from Glasgow wanting an outlet for his activities he was armed with the attributes of a training in observation, disciplined hands, and an inquiring mind. At that time William, in London, was sending letters home describing the fascination of his work in the great city and extolling the opportunities it provided. We may depend upon it those letters would often be read and discussed in the family circle. Most probably it was John's mother who wrote to her elder son asking him if he would do something for his young brother. Doubtless John felt a secret pride in William's success, and probably needed very little persuasion to undertake that journey to London in search of fame and fortune. Once in London, William's influence and example must have had a very powerful effect on his younger brother. William was not only a very successful teacher of anatomy but was a fashionable practitioner in midwifery, courted by the best people and popular among them. Withal he had a passion for collecting. He knew the art of the *préparateur*, which he first learnt from Douglas, to whom he had been apprenticed, and which was later furbished on his Paris visit. His preparations were among the best in London, and the museum he founded was generally regarded as one of the finest then in existence, being very readily accepted by the University of Glasgow after his death.

Inception and Growth of his Collection

It is often wondered where John Hunter secured his specimens in his early days, for it has been stated that while working as demonstrator for his brother any preparations he put up were placed in William's museum, and we know that several prepared by John are in the Hunterian collection in Glasgow. It is highly probable that, like other keen young men working in dissecting-rooms, he might remove some portions that were of special interest and take them to his lodgings to dissect in private; or he might hoard up some treasure, surreptitiously hidden away until such time as he felt he could use it. In these days, when the operating theatres so constantly supply the needs of our museums, it is perhaps forgotten what a wealth of pathological conditions is unearthed in the dissecting-rooms. It is recorded that Hunter collected when with the Army in Belle Isle, and when he came home in 1763 he was supposed to have something like 200 specimens of normal and diseased structures. In the Golden Square days he was mostly concerned with studies in comparative anatomy, and his great sources of supply were the animals that died in the menagerie then kept in the Tower. He never lost an opportunity of acquiring anything that would make a suitable preparation. Some were presents from friends. "If you will step in at Banks' in Soho Square, you will find the corpse of the fine Sierra Leone cat, the inside of which is at your service. The skin is to be stuffed for the British Museum." So wrote his friend Sir Joseph Banks, who was later President of the Royal Society and always his firm supporter. Other friends were roped in to help, and his old pupil Jenner was an unending source of supply. Further specimens were secured by purchase, and we know, in connexion with the skeleton of the Irish giant, to what length of monetary impropriety he was prepared to go rather than lose some specimen on which he had set his heart.

Hunter's Method of Work

The making of his preparations, the actual labour of creating his museum, must have been a colossal task, and there can be no doubt that the major part of this work fell on Hunter himself. Just think of the dissections, the macerations, the injections, and the display of the pathological material! Then there were the jars to choose and the specimens to be suspended or otherwise displayed, and the tops to be fixed. There were no ground lids to be cemented, but each jar had to be covered with pig's bladder or parchment, which had to be securely tied on; and after drying there was the outer cover of thin sheet-lead to be fitted, secured, painted, and probably varnished. Hunter certainly knew all about these processes, as we may gather from his remark concerning his brother-in-law, young Home, who was told that his damned clumsy fingers were all thumbs and that he would never have sense enough to tie down a bottle. Doubtless he would get help from those abo him and from his pupils, but his was the master hand, an indeed he was probably the only one who knew anythin about the art of preparation. Hunter himself was taught t make preparations during his apprenticeship to his brothe and there can be no doubt he made it a hobby and soo learned to excel. But, even if he did enjoy the work, th time involved must have been enormous. Anyone familia with the dissection of animals, and especially large one will know what a long time it takes: Clift speaks of Hunte standing at his work for hours. The same applies to patho logical specimens, for they must be prepared, displayed, an set up when fresh to get the best results. Then there is alway the recording to be done, descriptions to be written, labels t be fixed, and other duties of the kind. There is evidenc that Hunter was concerned with all these tasks.

Most of his experiments were done at Earl's Court, but th arrangements of his establishment there showed that room for dissection were not forgotten and that the work of makin preparations was provided for. It was there that he had th large copper for boiling bones, and we have the story of ho the body of O'Brien, the Irish giant, was taken there in th dead of night and hastily dismembered, and the parts boile so that the skeleton could be quickly prepared rather tha risk detection if the slower process of maceration was employe Just think what it meant to be engaged in the active wor of preparation almost every day for a period of 30 year Hunter's routine was to rise at 5 a.m. or earlier in summe and 6 a.m. in winter, and to go at once to his workroo where he remained until breakfast-time. Certain it is tha these morning hours were spent in association with those abo him, for it is recorded that on the very morning that he m his end he was particularly happy among his pupils. In on branch of his museum work he was not particularly carefu and that was the labelling of jars and the recording of date But Hunter was deeply conscious of the need for a caref record, and it was only the difficulty of applying some metho in the stress in which he lived that allowed this delinquenc to occur. No one, however, can say that Hunter was n systematic. He was constantly making notes on odd bits o paper, and these were all carefully sorted and entered up int his record books; but he was not careful about dates. H was also a great letter-writer and kept his correspondenc carefully.

The Workroom

Hunter's dissections and museum work were done in hi own house, for there were no laboratories or workrooms ke for him at the hospital, and he had to provide all that h required and to supervise everything that went on. At eac of his homes arrangements were made so that he could fulf these self-imposed tasks. There was undoubtedly good accom modation at Earl's Court, but the question of transport had t be considered. This was by coach, and it is interesting t ponder on the loads that Hunter's coach must have carrie to and fro in those busy days when it had to be a sort o covered wagon taking all kinds of human and animal remai from London out to the country and back. The methods o specimen-preparing that were used at that period are wort considering. There were the ordinary dissections, some o them very delicate and some of great size. Many of thes were mounted in spirit. Because of the difficulty of securin jars large enough and a sufficiency of spirit, some were prepare by the dry method. His original collection contained over 50 of this type. It was a tedious method, for the specimens ha to be very carefully cleaned, and packed or distended wit air; they were then painted with an arsenical preparation an hung up until dry. Finally they were carefully varnished an re-varnished, and as a rule mounted in jars to protect the Specimens made in this way will often last for many year and there are still some Hunterian preparations of this ki in good condition. Then there were the injected specimens a method in which Hunter excelled and for which he le directions—but they do not appear to have conveyed the secr of the art to those who have tried to follow in his footstep Corrosion specimens were also used. A great many of t pathological preparations were in spirit, which meant a lot work for their proper display and the fixing of the jar cover

The dry bone specimens had all to be macerated or boiled—both slow processes—to get the best results. There were also he calculi, the plants, foreign bodies, and the fossils, of which Hunter left so large a collection.

A great deal of Hunter's work must have been done in artificial light provided by candles. Heating must have been a difficulty, for there was nothing but open grates, which would probably burn coal. Judging by my boyhood experiences in the North, it is highly probable that in winter some of the fires would never be allowed to go out—not only for he purpose of heating the house but because it was the only method of securing a ready supply of hot water from a kettle on the hob and of obtaining a light. Clift mentions hat Hunter made spills from the scraps of letters on which he had previously made notes. Matches as we know them were not introduced until 1834, and if there was no fire it would be necessary to use a flint and steel with tinder-box to strike a light. Cold water may have been conveyed through pipes to a basin or sink in his workroom, for it is interesting to observe that among Hunter's belongings sold by auction after his death were wo leaden cisterns. The question of the disposal of waste must have been rather troublesome, for there was no water-carriage system, and dry closets and cesspools for the convenience of so large a household would require frequent emptying. Fortunately soap was plentiful and cheap, but after a heavy day and an evening spent in an atmosphere rendered grimy by a succession of smoky candles, there was no hot bath for Hunter before he retired to bed in the early hours of the morning. For his literary work there were only quill pens, as shown in Reynolds's portrait. His handwriting is good and legible but occupies a considerable amount of space, and we know that during those very full evening hours he illed an enormous number of notebooks. During the latter years of his life he dictated a good deal to an amanuensis, but there is no evidence that any sort of shorthand was employed. The manuscripts which were taken away from the Castle Street house to suffer so sad a fate at the hands of his brother-in-law, Everard Home, were said to fill a coach. Fortunately for us a considerable number were not destroyed. Hunter's dissecting and other instruments were of good quality.

With what we should consider to be such inconveniences there were bright features, for Hunter was saved the tyranny of the telephone and long out-of-town journeys. Had he done nothing more than care for his museum, his pupils, his lectures, his writings, and supervise his amanuenses and artist he would have been very fully employed and would have accomplished a great deal of which he might be proud. But these were really only side-lines, for he conducted a very large practice. His professional work began immediately after breakfast, when he saw patients at home. It is said that those waiting were so numerous that they often invaded his wife's drawing-room. At a fixed hour he left home in his coach to make outside visits and for hospital practice, and he never delayed his departure even if persons of importance were still waiting to be seen. He did not return home until four o'clock, which was then the usual dinner hour; after dinner he commonly slept for an hour on a couch in what was called the afternoon bedroom. Then began what must have been some of the most strenuous work of the day—letter-writing, case-recording, the description of his dissections, and the task of laboriously turning out those iterary works which eventually made for him a fame which has been lasting. In addition, for years he lectured at his own house every alternate evening from April to October. Can we assume that he was so intensely occupied and so absorbed in the practice of his profession that he found no time for affairs around him? No one could have been more single-minded or more absorbed in his pursuits. Assuredly he scorned delights. and certainly no one has ever lived more laborious days.

The Disaster and After

On the night of May 10, 1941, the College Museum was struck by a heavy high-explosive bomb and showered by incendiaries. As a result the greater part of the Museum and some parts of the College were destroyed, and about two-thirds of our collections vanished in the conflagration. The story of the measures which had been taken from 1938 onwards to guard against such a tragedy, the details of the disaster, and the steps taken to salvage and care for what remained of our treasures has been admirably told by Prof. A. J. E. Cave, the Assistant Conservator, in the Scientific Reports of the College for 1939–40 and 1940–1. It is a sad chapter in College affairs, and has caused much regret and unhappiness to lovers of the great museum we so much treasured. Clearly our duty is to look to the future and to consider plans with ways and means for complete restoration.

The Future

The disaster has not only imposed a greater responsibility than ever before but has provided an opportunity of which it is necessary to make use. After some months of hard work the Museum Committee was able to present to Council a suggested plan for the restoration of the Museum, together with many ideas on future developments. The Museum will be reborn in circumstances different from those which existed when it first came into being over 130 years ago. Then there were no museums devoted to anatomy and pathology in this country, and only one or two London hospitals had a few preparations for the use of their pupils. Now all medical schools up and down the country have museums, some of them excellent, so that from the purely vocational aspects of medical education the country is well provided. But there is a large floating body of students in London, mostly Empire students not owing allegiance to any school in the Metropolis, who naturally look to the College for museum facilities and who must be catered for. Other museums, and notably the natural history collections at South Kensington, are now in a position to carry out many of the activities previously shouldered by the College in the field of zoology and natural history, and others may be expected to develop—for instance, in anthropology.

Broadly, the conclusions of the Museum Committee, accepted by Council and by the Hunterian trustees, are that the museum should be restored and built up around the surviving collections to illustrate the development, structure, and functions of man, together with the accidents and diseases to which he may be a victim, with such reference to the animal kingdom as may help to elucidate the problems involved. The part of our museum that earned us an international reputation was the physiological and comparative anatomy series. In any event that would be the part most difficult to replace and, alas! it has suffered severely. The restoration of the pathological sections will be much less perplexing. One of the first questions that had to be settled by the committee was how to dispose of the surviving Hunterian preparations. The first inclination was that they should be kept together as a precious relic and a memorial to the work of our founder. The idea of having a room set aside, as a sort of shrine, in which they might be exhibited together with any other Hunterian relics, was most attractive and made a strong sentimental appeal. But more mature reflection convinced us that this would not be in keeping with the Hunterian tradition, and that it would be much better to have them allocated each in its proper section of the general collection, where they might act as a leaven and a stimulus. No one would wish to claim that all the Hunterian preparations are now of great value; some have served their purpose, their usefulness having been superseded by advances since Hunter's day, and some are so deteriorated as to be of little but sentimental value. Others were classical and some unique, and some possibly guarded secrets of nature which up to the time of their destruction had not been divulged. Those most interested and best able to judge agree that, so far as possible, destroyed Hunterian specimens with a lesson to teach or recognized as classical or potentially valuable should be replaced. An idea very much in my mind is the suggestion that when the specimens can be safely returned to the College an exhibition of the whole surviving Hunterian collection should be set up in one of the rooms together with all the existing relics of Hunter that can be got together. This should be attractively set out according to the original plan, and should be on view for several months, so that those who are interested may have the rare privilege of seeing assembled together what remains of the collection. Photographic and other records should be made, and these would serve in years to come to interest those who had not enjoyed the opportunity of seeing such a unique exhibition.

Among many who have talked about the restoration of the museum there are not a few who dread that the new museum will be cluttered with animal skeletons. There are some who have no use for the wonders presented by the bony framework of the elephant, the giraffe, or the whale, and no veneration for extinct monsters like the Irish elk or the megatherium. They may be astonished to hear that it was never the policy of the College to collect such taxonomic exhibits, but those that came to us in various ways were not rejected. But if a skeleton or part of a skeleton, irrespective of its size, is necessary to display some feature in comparative anatomy or physiology which leads to the better comprehension of the structure and function of man, then let us hope it will be preserved and exhibited. The same general principle should apply to the soft parts of animals, however large or however minute. Just fancy the interest of comparing the oesophagus of the giraffe with its insignificant counterpart in man! Perchance the secret of achalasia may be disclosed in the study of its neuro-muscular mechanism. Then how truly awe-inspiring to be able to re-create Hunter's wonder when contemplating the enormous aorta of the whale. And what bearing may the structures of that great creature yet have on the understanding of some of the problems of aeronautics? It is the intention to keep the museum up to date as a collection by replacing deteriorated specimens and by constantly adding better ones as these become available. Only the very best obtainable should be found on our shelves. But there is another point, and that is the question of the history and after-history of the cases from which specimens have been obtained. Many a poor-looking specimen is valuable because of its clinical history, and many another grows in value as the long after-history of the case adds to its interest and importance. The renewal and follow-up department must be much more active than ever before. Personally, I would like to see the day when it would be a distinction to have specimens accepted by the College because of their excellence and the complete histories with which they were accompanied. Specimens should be accepted and retained only because of their value, and the days are long past when the distinction of the donor could claim precedence over the distinction of the gift. Special collections should be accepted only with the proviso that the specimens may be dispersed among the general collection if this is considered best in the interests of the museum.

Another idea I want to bring forward is the value of special but changing exhibits. The restored museum should possess a large demonstration room where special exhibits could be put up from time to time and kept on display for a month or more. A section on the anatomy of approach is somewhat of a new idea, and would be intended to display the anatomy of operative incisions. How often has the novitiate wondered exactly what are the structures encountered and to be divided or thrust aside in carrying out the exposure of the kidney, excision of the rectum, or the exposure of the Gasserian ganglion? For each operation a series of special dissections would have to be available and alternative routes of approach would have to be illustrated. I am convinced of the value of such a plan, and am most interested to find that it was employed by James Douglas, who died in 1742, and who is remembered by the peritoneal pouch to which his name is linked. The section of general pathology was of the greatest value, embodying as it did the very kernel of the Hunterian idea. This should be restored in its entirety, and there may be directions in which it could usefully be extended. The old museum contained the most remarkable collection of calculi—about 1,000 in number—of all sorts, which were classed mostly according to the parts of the body in which they were found. In the future museum, considerations of the formation of calculi—calculus disease—should provide a more thought-provoking section. Then there is the idea of group exhibits where the ravages of any one condition are shown together irrespective of the number of the regions of the body that may be involved. A medico-legal section is very badly needed, for there is none of any moment in a public museum, and it would seem a very proper activity for us to undertake. I was very much impressed with such a collection in Buenos Aires, in which most beautiful wax models were largely used to supplement the exhibits.

Gynaecology and obstetrics were always well represented in our museum, but the specimens might well be brought more in line with present-day knowledge. There is no branch of surgery which lends itself better to museum illustration, and there ought to be no difficulty in rebuilding our collections and in making them second to none. The odontological collection was fortunately spared. Under the devoted guidance of its honorary curator, Sir Frank Colyer, this branch of surgery which originally owed so much to Hunter, was very worthily represented. Each of the special senses must have sections devoted to its exhibition, as in the past, but this must not prevent certain conditions being included in the section of general pathology or elsewhere if some principle can thereby be the better illustrated. In view of the well-directed activities of the Wellcome Foundation I think we might properly restrict our historical collection to relics of Hunter and his immediate associates. A large part of our surgical instrument collection has survived, and might well form the nucleus of an exhibi to illustrate their evolution and development. Sections for venereal disease, anaesthesia, blood transfusion, and wound treatment would appear to be necessary, and will certainly prove useful and interesting. A standard collection of the very best *x*-ray films should not be excluded from such a museum as we have in mind. The results of surgical intervention—i.e., the after-results of operations—should be fully illustrated, and might form an increasingly fascinating exhibit Similarly the results of experimental surgery should be demonstrated by specimens. Of the thousands of experiments carried out, how little in the way of museum records is available. In other ways there should also be a closer association between the department of experimental surgery and our museum Another good feature which must be continued and developed was the annual show of new specimens, always on exhibition in connexion with the Annual Meeting of Council in July.

In order that we may help serious workers to extend knowledge it will be necessary to have a large amount of store material, not merely tucked away, but easily accessible and properly catalogued or indexed. Facilities should be provided for its close examination, even if dissection is necessary. The use of such material could not be very open-handed, and only accredited workers who seriously wanted to obtain information which they could not get elsewhere should expect to be allowed such facilities. I also have in mind proper study rooms, where those engaged in a particular piece of work could keep their specimens and could work on them without necessarily having to reassemble their material each day. For some years there has been much talk of research in the profession, but this has usually been in terms of laboratory work and usually animal experiments. Many people forget how much research is waiting to be done in other directions, and there is certainly a great deal that might be carried out in any well-equipped museum. It is especially important that we should provide for the very many keen young surgeons who are working in and about London, and they should be encouraged to make use of the opportunities for study which our museum affords We should aim at making our collections the most famou in the world, but we must not assume that other museums have stood still, and it is most important that we should have information as to what may be going on elsewhere, so tha inquirers might be helped by direction to the proper quarter for this and other purposes a museum bureau would be mos useful.

Conclusion

Hunter's saying, "Why think; why not try the experiment?" has been handed down as a sort of tradition; but to look and see and to verify everything by observation is to carry out the same fundamental principle, which is so revealing tha its recognition fully justifies the existence of our museum Everything that we can learn about Hunter encourages th re-creation of the very best museum that can be assembled We want it to be a Mecca for inquiring students from every part of the world. Its reconstruction will be slow; it mus be patiently done, and it must be thorough. We must plod on and on till the task is well under way, knowing full wel that it can never be completed. There is always the exampl of Hunter's driving force to encourage us, for "there wer no drones in his hive."

INFLUENZA EPIDEMICS AND THE INFLUENZA VIRUSES

BY

C. H. STUART-HARRIS, M.D., F.R.C.P.
Lieut.-Col., R.A.M.C.

LECTURE II

n my first lecture I attempted to outline the history of fluenza epidemics in this country in recent years and to escribe the characteristics of the human disease invoked by e influenza viruses. In the present lecture I wish to refer ainly to the study of immunity to the viruses under natural r experimental conditions and to the development of possible ethods of control of influenza.

Immunity to Influenza Virus Infection

From the earliest days of work with influenza virus in the boratory the subject of immunity and of artificial methods f producing resistance to infection has been given constant ttention. Much has been learnt; much probably remains ndiscovered. The ability to control conditions and to standardize procedure in the laboratory has resulted in the accumu-tion of a valuable body of knowledge of immunity in xperimental animals, much of which is probably applicable the more complex immunity in man. Most of this work as been carried out on virus A, but there is no reason suppose the results do not apply to virus B also. More cently, however, experiments on human volunteers have been rried out, with the result that knowledge concerning the uration of immunity and the effectiveness of various methods immunization in man is accumulating rapidly.

Immunity in Experimental Animals

Ferrets are especially suitable for studies of immunity cause of the resemblance between the infection induced by e viruses in this species and that occurring in man. Immediely after an attack of the disease the ferret is completely mune to reinfection, antibodies are present in high titre in e serum, and the immunity is broad-based so that heterogous strains of the same major type are resisted in addition the homologous one. There is even, in the days of early nvalescence, a cross-immunity between swine influenza virus d virus A, though not between virus B and virus A. Heterogous cross-immunity of this type may be present, though tibodies to the heterologous strain may not be detected in e serum. As time passes the homologous antibody level gins to fall and susceptibility to reinfection returns. However, mologous antibodies are still demonstrable in the serum when infection is possible, and the second attack, though accomnied by fever and nasal symptoms, is usually less severe and not followed by the development of lung lesions if a lunglapted strain of virus is used for the reinoculation.

In an attempt to illuminate the apparent failure of antibodies -that is, of humoral immunity—to explain the phenomena bserved in the ferret, Francis and I (1938a, 1938b, 1938c) udied the histological changes in the nasal mucosa following rimary inoculation and reinoculation with virus A. We found at a cycle of events occurs in the respiratory portion of e nasal mucosa during primary infection. The ciliated ithelium undergoes complete necrosis, leaving only a single sal layer of flattened cells, and, after three days, repair by rowth of a many-layered pseudo-stratified type of epithelium ts in. Ciliated epithelium is not re-formed until a fortnight three weeks after infection, but by the fourth week the mage to the epithelium has been largely repaired. The ratified epithelium present for several days during conlescence interested us very much, and we were able to show at this modification of the normal nasal mucosa, which is resent when immunity is at its height, is resistant not only reinoculation of virus but to unrelated physico-chemical gents. Zinc iontophoresis or simple instillation of zinc lphate intranasally in normal ferrets produced an acute ecrosis of the epithelium very similar to that of influenza, d repair and regeneration followed a similar course. The rret convalescent from influenza showed, in the second week, a complete resistance of the nasal mucosa to destruction by iontophoresis, and the epithelium revealed no histological changes after this operation. As the epithelium of the convalescent animal became more normal, destruction by ionization again became possible, until at four weeks a normal reaction was obtained. The converse experiment of ionization of the nose followed by instillation of virus gave, however, no evidence of resistance by the regenerating epithelium to the virus.

These studies demonstrated to us that virus infection was followed by morphological changes, which were of a temporary character only and were therefore inadequate by themselves to explain the observed immunological phenomena. There seemed to us to be an analogy to the experiments of MacNider (1937) on the morphological changes of fixed tissue cells in the liver and kidney resulting from damage by chemicals. Whereas chemical tolerance to those agents was found by MacNider to be accompanied by a permanent modification of the liver and kidney structure, our abnormal nasal epithelium, on the other hand, was only transitory, and with the reappearance of a normal epithelium the non-specific resistance to damage was lost.

The nasal mucosa of ferrets exposed to reinfection at a time when immunity from the first infection had waned underwent necrotic changes similar to those seen in the first attack. Differences were discerned, however. Areas of epithelium sometimes remained normal, so that the necrosis tended to be focal in type, a more rapid repair followed the necrosis, and often the epithelium was not reduced to a single basal layer by the reinfection. This appeared to indicate a conditioning of the nasal mucosa by the first attack, so that the infecting agent was more readily repulsed and the damage more speedily repaired. Furthermore, if the ferret had had two previous nasal infections a solid immunity to a third or fourth inoculation might be encountered and then the nasal mucosa showed no histological changes at all. We studied the antibody levels of some of these ferrets prior to reinoculation, and were led to believe that the actual titre of circulating antibodies at the time of the immunity test was of fundamental importance.

These studies also afforded some explanation of the reaction observed in the ferret after subcutaneous inoculation with the virus. It has already been mentioned that infection does not follow introduction of virus by this route, and though antibodies subsequently develop in the serum the animal is not immune to nasal instillation of the virus, though possibly resistant to the more delicate test of contact infection (Smith, Andrewes, and Stuart-Harris, 1938). If parenteral inoculation of virus is given to a ferret in a state of waned immunity following an actual attack, the immunity may be boosted once more and a solid resistance to a second intranasal inoculation of virus may result. The production of a state of immunity by the re-installation of a high antibody level in an animal whose nasal mucosa is conditioned by previous infection can be readily visualized. Also from experiments on the immunization of ferrets, Francis (1939) was able to show that a considerable quantitative relationship existed between the degree of immunity following subcutaneous vaccination, the level of circulating antibodies at the time of the immunity test, and the amount of virus which was given in the vaccinating dose. Artificial immunization in the ferret is thus dependent for its success on the amount of actual virus antigen which is introduced parenterally; but the susceptibility of the nasal mucosa to infection, aided perhaps by the remoteness of the epithelium from circulating antibody in the serum, makes it impossible to reproduce the complete immunity which follows nasal infection.

Immunity in mice appears to be less complicated than that in ferrets, and it is also easier to produce a state of complete immunity by artificial immunization. The changes in the lung following intranasal inoculation with virus A have been studied by Oakley and Warrack (1940) and correlated with the presence of antibodies in the serum. The production of actual lung lesions was found to be essential with mouse-adapted strains of influenza virus for the subsequent development both of antibody and of immunity. Immunity developing after intranasal infection was broad-based, and was effective against heterologous virus A strains even in the absence of good levels of antibody against such strains. Other observers have found it to be possible to obtain immunity after intranasal infection of mice in the absence of lung lesions, but only, however, if the virus used is not of mouse origin. Thus Burnet and Clark (1942) showed that unadapted human virus would both immunize and produce antibodies even though no lung lesions were produced, and Eaton and Beck (1940) obtained immunity without lung lesions by using ferret virus or tissue culture from chick embryos.

Because mouse-passage strains of virus must be used in high dilution if the production of lung lesions is to be avoided, it seems that these results simply mean that the effectiveness of immunity after actual infection in mice is closely dependent on the quantity of virus which has actually been administered. The immunity following parenteral inoculation of mice with virus preparations has been closely studied. Inasmuch as massive doses of living virus have to be given intraperitoneally (Rickard and Francis, 1938) in order to produce infection of the lungs by this route, the results of parenteral inoculation with living or with inactivated (formolized) virus are rather similar. Antibodies are most rapidly produced, however, after the introduction of living virus intraperitoneally, and persist somewhat longer than when inactivated virus is used (Oakley and Warrack, 1940). The results of repeated inoculation with either virus preparation are better than those of a single dose. The influence of the subtle changes of past infection in mice is well illustrated by the fact that although antibodies to heterologous strains of virus A are poorly developed after either parenteral or nasal introduction of virus, the immunity to heterologous virus following parenteral immunization is much more feeble than that following actual infection. Eaton and Pearson (1940) noted that about 10 times as much virus was needed to protect against heterologous strains as against homologous ones after intraperitoneal immunization either by living or by inactivated virus. Eaton (1940) also estimated that, given by the same route—that is, intraperitoneally—about 30 times as much inactive virus was needed to produce the same degree of immunity as active virus. The importance of the amount of actual antigen in the production of an immunity which is broadly based and effective against heterologous strains is thus clear. The superiority of immunization based on an actual infection, even if this is inapparent, is also obvious. Two further factors have been shown to operate adversely in the case of parenteral immunization. The presence of foreign protein from the host species used to prepare the vaccine has an interfering action on the effect of the vaccine in stimulating antibody formation, and the intraperitoneal route of inoculation is more favourable than the subcutaneous one (Andrewes and Smith, 1939).

Many of these facts which have been elicited from studies with mice have a bearing on human immunization, as we shall see later. Meanwhile, it is necessary to mention the effectiveness of prophylactic administration of immune serum, either from convalescent ferrets or from hyperimmunized rabbits or horses, in the influenza virus infection in mice. Laidlaw, Smith, Andrewes, and Dunkin in 1935 showed that serum given intraperitoneally saved life and diminished the extent of lung lesions if given either before or after intranasal infection. More recently, others (Henle, Stokes, and Shaw, 1941; Taylor, 1941b) showed that the serum was much more effective as a prophylactic if given intranasally, and that some effect was demonstrable even up to 10 days after serum introduced by this route. Trial of the method in ferrets has not, however, given results comparable to those obtained in mice (Zellat and Henle, 1941). Unpublished experiments of Glover and Andrewes, to which I am kindly allowed to refer, indicated that some protection could be given to the lung of a ferret, but that it was not possible to protect the nose by inhalation of atomized serum or by exposure to a coarse spray. The intensity of the infecting dose of atomized virus to which the serum-treated ferrets were exposed was carefully controlled, and even a low degree of immunity was unlikely to have been overlooked.

Immunity in Man

(a) Natural Immunity

At least three mechanisms are now known to be concerned in determining resistance or susceptibility in man to influenza virus infection. The first—namely, the development of antibodies with specific neutralizing power for the virus—has been most studied. The distribution of antibodies to virus A the population in interepidemic times has been found to related to age. Children other than newborn babies have leas and adults of middle age have most antibodies. Cyclic changes in the general level of antibodies in the serum a correlated with the occurrence of human epidemics in th levels are highest immediately after an epidemic and lowe before an outbreak, while the individuals with the highe levels after infection undergo the greatest proportional chang with the passage of time. Some individuals, particularly tho in the middle range of antibody levels, possess remarkab stable antibody titre over periods of many months. Complement-fixing antibodies also undergo cyclical changes, b are at their highest levels for a shorter period of time aft an epidemic than are neutralizing antibodies. The fact th sharp changes in titre of antibodies accompanied actu infection and that both clinical and subclinical attacks a associated with changes of a similar magnitude has alread been mentioned. So far virus has only rarely been recovere from clinical influenza unaccompanied by serological chang (Adams, Thigpen, and Rickard, 1944), but it is known fro deliberate infection experiments that clinical symptoms can times occur without serological alteration, and the significan of the varying percentage of cases in the various outbrea which yield neither virus nor antibody change (influenza Y can be interpreted in various ways, as previously pointed ou Apart altogether from diagnosis, however, the antibody chang during infection are of considerable importance in relation susceptibility or resistance to attack. All observers are agree that a majority of cases of influenza are drawn from th population group which has the lowest levels of antibody befo infection, but that individuals with all levels of antibody yie cases during an outbreak.

The accumulation of all this mass of information has bee the work of many observers in all parts of the world, ar evidence on which these statements are made was fully reviewe by Burnet and Clark in 1942. Our own slender contributio may be referred to briefly. In 1936 Andrewes and I bled group of 50 medical students at St. Bartholomew's Hospita estimated their neutralizing antibodies, and then observed th experience of this group during the 1937 epidemic. Cases we scattered through all the various levels of pre-epidemic antibody content, and though we did not prove virus A infecti in all cases, the uniformity of experience in this outbrea indicated the probability of this diagnosis. A large number cases of influenza B were observed in 1943 and investigat by Hirst's test. There was a fairly marked scatter of cas (Chart VII), with antibodies during the acute febrile stage very different levels. Also, the number of B cases was proportionately greater in those with low antibody level in the fi specimen of serum. The influenza Y cases whose antibody lev showed no change had on the whole higher levels of antibo than the B cases, but some cases had low levels. The correlati between the actual multiplication of antibody content in th blood of the B cases and the original content of antibody w definite, and has been noted by other observers in bo influenza A and B (Chart VIII). It means, as Hirst and othe (1942) have pointed out, that the same total quantity of antibody is added to the serum of the various cases, and that th is many times the amount already present in those with lo levels and is relatively less in those with high pre-existing leve of antibody. Comparison between severity of clinical infecti and pre-existing antibody level or degree of multiplication antibody failed to show any relationship either in virus influenza (Chart IX) or in virus A influenza (Chart X). Th agrees with the known fact that an individual can have subclinical attack or a clinical infection at any pre-existi level of antibody.

One last fact which must be mentioned concerning the antibody response to infection is the degree of change in the seru for heterologous strains of virus. There has been some controversy between various workers as to whether huma respond to infection with antigenically distinct types of vir with the same degree of specificity for homologous strains does the ferret. The balance of evidence now favours the vi that the amount of antibody in the serum in the acute sta is less when tested against the homologous virus than wh heterologous virus is used. The actual amount of increase in antibody is also greater for antigenically related than for antigenically distant strains of virus, as our own results (Andrewes, Smith, and Stuart-Harris, 1938) indicated. Magill and Sugg (1944) have recently re-emphasized the importance of this finding in connexion with diagnosis. The existence of a multiplicity of antigenic types of the same major strains during any one outbreak, such as has actually been proved, must also have an important influence on the effectiveness of the resistance of the individual whose antibody titre may be adequate to produce immunity against some but not against other types of virus.

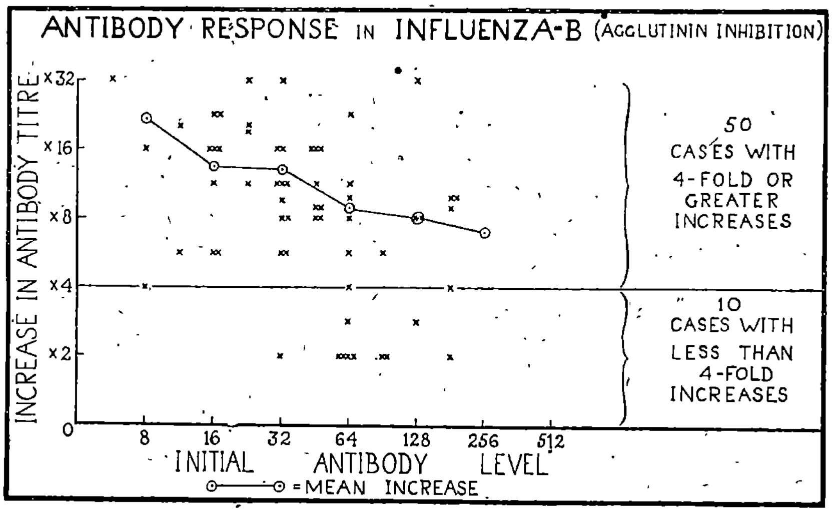

CHART VIII

The results obtained from study of human infection indicate that no critical level of antibody exists below which there is susceptibility and above which there is resistance to infection as was thought originally (Hoyle and Fairbrother, 1937; Francis *et al.*, 1937). Burnet (1944) has recently emphasized that the fundamental fact concerning immunity to influenza is that in all recent epidemics never more than 50%, and usually under 20%, of the population experience clinical attacks during an outbreak. It has been shown that cases of actual clinical infection are chiefly drawn from individuals with the lower levels of antibody (Rickard, Lennette, and Horsfall, 1940), but that cases can occur throughout the range of antibodies. Yet the 70-odd% of the population which escapes influenza must include many individuals with low antibody levels, though during the outbreak some—perhaps in widespread epidemics the majority—develop increase in antibodies irrespective of clinical attacks. It is in these individuals that the explanation of antibodies as the chief factor in the resistance to infection breaks down. To what, in fact, do they owe their immunity? Doubtless some escape contact with the virus altogether, but this does not account for those who develop subclinical attacks.

Studies of groups of individuals who have been deliberately infected by spraying with virus A or by inhalation of atomized virus A have given much clearer correlation between antibody levels and immunity than the experience during natural infection (Burnet and Foley, 1940; Henle, Henle, and Stokes, 1943). It appears that standardization of the dose of infection produces clinical attacks only in those individuals with low antibodies in their blood before infection. In the experiments of these workers, 26% and 36% respectively of normal individuals experienced clinical attacks and more developed subclinical infection. In the much more intense exposure to virus B by Francis and others (1944), when clinical attacks were produced in 90% of individuals by inhalation of atomized virus, there was much less correlation with antibody levels. Four months after the original spraying Francis could again produce clinical attacks in 90% of the group sprayed initially, in spite of the fact that they still had an enhanced antibody level as a result of their initial experience. Possession of good antibodies was somewhat correlated, however, with shorter and milder fever. Besides demonstrating the evanescence of human immunity to actual infection by influenza virus, Francis thus showed that the defence against infection could be broken down if the intensity of the infecting dose was sufficiently great. We may perhaps deduce that the intensity of

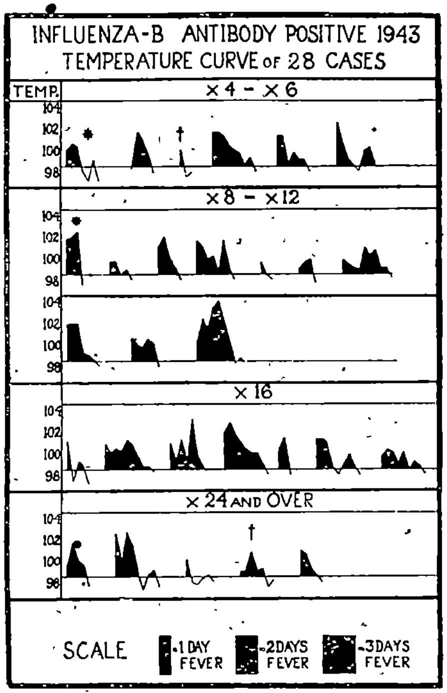

CHART IX.—* Two cases with high initial titre. † Two cases with low initial titre. x 4, etc., indicates the increase in antibody titre (Hirst test).

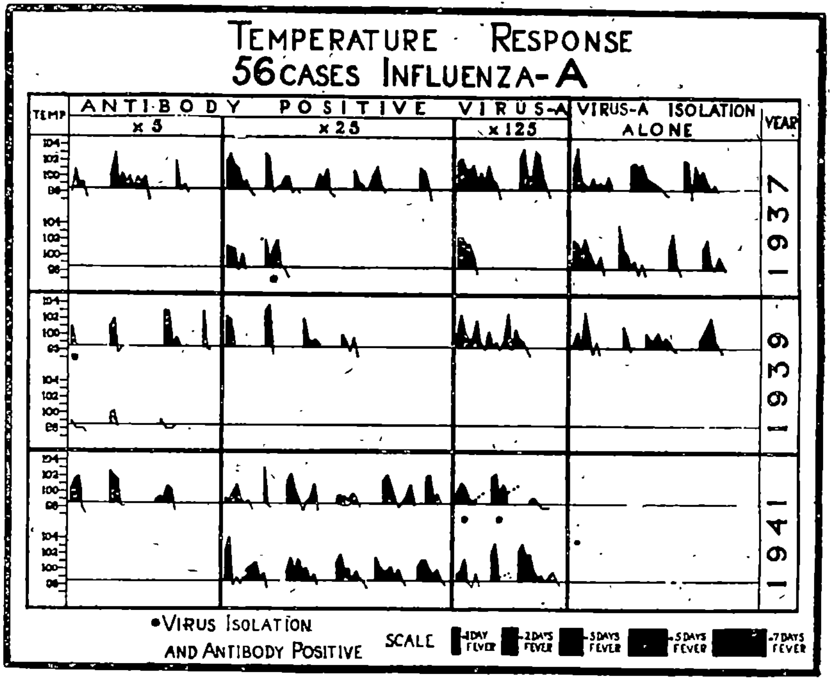

CHART X.—x 5, etc., indicates the increase in antibody titre (mouse neutralization test).

natural infection during an epidemic is much less than that used by Francis and probably less than that of the earlier workers with virus A, in view of the lower percentage incidence of infection observed during natural outbreaks. May it be that repeated exposure to infection during an epidemic breaks down in some individuals the resistance conferred by a high antibody level? Also, may the escape from clinical attack by some individuals with low antibodies be attributed to the fact that they are lucky in receiving just enough virus to cause a subclinical but not enough to cause an overt infection? Other mechanisms governing resistance probably do exist, however, and one of these is the natural defence of the nasal mucosa to attack.

No observations on the changes in the nasal mucosa which accompany human influenza appear to have been made, but a humoral system of defence based on the property of virus inactivation possessed by nasal secretion has been studied both by Burnet and his co-workers (1939) and by Francis (1941). Controversy still exists as to the nature of this substance, which has a wide range of activity against viruses other than influenza. However, different individuals possess different amounts of it, and Francis showed that there was a correlation between the inhibitory activity of the nasal secretion to influenza virus and the influenza antibody present in the blood; and a sharp increase in virus-inactivating power of nasal secretion accompanied infection (Francis and Brightman, 1941). In connexion with this it was also shown (Francis *et al.*, 1943) that an increase in the amount of inhibitory substance in nasal secretion followed subcutaneous immunization accompanied by successful stimulation of antibody production. Burnet, on the other hand, considers the substance to be an enzyme in character, and is inclined now to attribute less significance to its action than at one time (Burnet and Clark, 1942). If, however, both chemical and cellular defence of the nasal mucosa, including the capacity of the nasal epithelium to regenerate rapidly after attack, is considered, it must be obvious that the first line of defence against the virus is probably important. A more doubtful mechanism, which may or may not play a part in the production of clinical phenomena, has been unearthed by Beveridge and Burnet (1944), who studied the skin reactions to inactivated influenza viruses inoculated intradermally. They found that boiled chick allantoic fluid from eggs infected with either virus A or B was capable of eliciting an erythematous skin reaction in both children and adults. No correlation between level of antibody and liability to a positive skin reaction was found, but in children positive reactions were obtained only when possession of some demonstrable antibody suggested past infection or exposure to the virus.

These observations suggested that allergy may be important in determining clinical reaction to influenza virus. Observation on animals has hitherto given little indication that allergic reactions were important. However, Shope and I, in 1938, carried out a few unpublished experiments in which pigs were inoculated intraperitoneally with immune horse or convalescent pig serum and were subsequently inoculated intranasally or exposed to contact infection by swine influenza virus and *Haemophilus influenzae suis*. There was a definite indication that the serum-treated animals were in some way sensitized, because fever and clinical symptoms consistently developed some hours earlier in these animals as compared with the controls who did not receive serum. We were, however, more interested at that time in the possibility of attenuating clinical attacks, and this we failed to accomplish. Allergic reactions in man have been suggested by the deliberate infection experiments of Bull and Burnet (1943), in which symptoms were commoner after intranasal reinoculation than after a first intranasal inoculation with a modified attenuated strain of virus B. An increased incidence of symptoms on reinoculation three to four months after the first spraying of volunteers with the virus occurred in spite of enhanced antibody levels in the serum. The strain of virus used did not produce febrile reactions, and the occurrence of nasal symptoms after both first and second spraying bore no relationship to the subsequent development of an antibody rise in the serum. By the criterion of demonstrable antibody rise, infection was produced in more than 90% of the 23 individuals by the primary inoculation, but in only two instances in the second inoculation. Dissociation of this type between nasal symptoms and immune reaction may be related in some way to the type of infection produced by attenuated viruses, and it was not encountered by Francis (1944) in his reinfection experiments with less modified virus B. Francis, far from demonstrating an increased tendency to symptoms in individuals subject to reinoculation, thought that individuals with the highest antibody titres had less reaction after inhalation of the virus. Time alone will show whether allergy is of much importance in relation to the natural disease.

(b) Artificial Immunization in Man

The discovery of the aetiological agent of human influenza was soon followed by attempts to produce immunity with virus preparations, and these have been actively pursued by several different groups of workers. Emphasis has been largely placed on experiments designed to produce active immunity, and the various workers in this field have concentrated their energies along two distinct lines of attack. British and American investigators have tended to develop methods of immunization based upon the fact that most individuals have, at one time or another, been subject to nasal infection by the virus, and therefore the human problem is essentially one of reinforcing a waned immunity rather than that of developing one in a previously uninfected host. They have therefore tried various methods of immunization by the subcutaneous route, arguing that if a sufficiently intense antibody response could be produced the nasal mucosa could be left to take care of itself. In contrast, Australian workers have concentrated on the development of an attenuated virus strain which could be given intranasally without producing clinical reaction yet producing an effective immunity by reason of its attack on the nasal mucosa, which would be unaffected by subcutaneous inoculation. Such a strain of virus would ideally resemble the yellow fever 17D virus, which has been so successfully used in human immunization against yellow fever (Theiler and Smith, 1937).

Early work in Britain and America was concerned with the demonstration that subcutaneous inoculation of virus enhanced the antibody titres of those inoculated. The fact that inactive formolized virus appeared to be an effective antigen in man was demonstrated at an early date. Furthermore, one inoculation produced as good a rise in antibodies as did several doses. However, detailed study of the factors concerned in determining the relative efficiency of various vaccines in producing antibodies has been chiefly pursued of recent years in America. Hirst, Rickard, Whitman, and Horsfall showed in 1942 that there was a considerable variation in the human antibody response to the same preparation of virus given subcutaneously. The rise in antibodies was correlated with the pre-vaccination titre of the serum, so that the actual amounts of antibody produced by individuals with originally different amounts of antibody were approximately the same as in the case of actual infection. Secondly, the antibody rise induced by subcutaneous vaccination was evanescent and titres had dropped considerably six to nine weeks after vaccination. Thirdly, the antibody response increased in proportion to increase in the amount of virus antigen which was injected. The most concentrated preparations of antigen which were inoculated produced antibody responses of a magnitude similar to those encountered as a result of actual infection. Fourthly, inactive virus, especially in a relatively protein-free medium such as chick allantoic fluid, was as effective an antigen as living virus. The incorporation of a strain of distemper virus originally thought by Horsfall, Lennette, and Rickard (1941) to exert an adjuvant effect on the influenza antigen was not found to be helpful. Bodily and Eaton (1942) added a fifth factor, which would be expected to be of significance if the results of experiments with animals are applicable to man. They compared the specificity of the antibody response following vaccination with that occurring in actual infection with virus A. The sera from vaccinated individuals were more specific in their antibody content to the strain used in the vaccine than were the sera from infected individuals to the infecting strain, although these too showed a limited degree of strain-specificity.

Notwithstanding the apparent drawbacks associated with the use of a virus vaccine subcutaneously, several trials have now been carried out which indicate that such a method of immunization is not only practicable but gives results which indicate a measure of protection in vaccinated individuals. Our own record in connexion with such studies has hardly been brilliant. In 1937 we employed a formolized vaccine made from filtrates of the lungs of mice infected intranasally with the W.S. strain of virus A—a strain which is apparently particularly specific in antigenic constitution. Only 30 volunteers were vaccinated at an adequate time prior to the 1937 outbreak, and none of these or their controls contracted the disease. Some hundreds of other subjects were also immunized with the same vaccine, but the immunization was too late in the course of the epidemic for reliable data to be obtained. Several instances occurred of influenza A in vaccinated individuals, however, and all the virus strains recovered in the outbreak were relatively remote antigenically from W.S. We wondered if the antigenic difference between vaccinating and infecting strains was the cause of the poor result.

In 1938 we immunized 500 boys at the Naval training school at Shotley in November and December, some with a polyvalent formolized mouse-lung vaccine containing the broadly antigenic P.R.8 strain and also the W.S. strain, and some with W.S. virus vaccine only. When influenza broke out in Jan., 1939, it did not affect this particular institution. A small wave of mild influenza occurred in April, however, and we were able to recover influenza virus A from some of the cases. During the fortnight when virus A influenza was affecting the unit, 4.35% of the vaccinated and 5.4% of the controls suffered clinical attacks. The differences in incidence in the groups receiving the two vaccines were insignificant. We thought that the interval of four months between vaccination and infection meant that the effects of the vaccine had worn off by the end of this period. It was also surprising that this institution experienced its outbreak of influenza so late in the year, for other areas were affected in February and March. Again, we wondered if the number of vaccinated individuals in the community in these months was proportionately high enough to confer temporary immunity on the whole group.

Since the war we have for various reasons been unable to undertake the manufacture of enough virus vaccine for field trial. However, in 1940 a considerable quantity of the combined formolized virus A and distemper vaccine thought by Horsfall and others (1941) to be such an effective antigen was made available to the Medical Research Council for use in this country. In spite of the relatively poor antibody responses obtained on preliminary trial, we decided in 1942 to utilize the vaccine in a controlled field trial in the Army. Some 12,000 volunteers in the various Home Commands were inoculated and a similar number were set aside as uninoculated controls. The vaccination was completed by Dec., 1941, but no outbreak of influenza occurred at all in the next three months, and such tests as were carried out on sporadic cases of influenza failed to give serological evidence either of influenza A or of influenza B.

Thus we reached no conclusion as to whether this vaccine had been beneficial or not. However, Horsfall, and also Brown and his co-workers (1941), used the same type of vaccine in 1940 on some thousands of individuals, and concluded that a real reduction in the incidence of clinical influenza occurred during a subsequent virus A epidemic. The best results were that a 50% reduction occurred in certain of the vaccinated groups of individuals, but the results in other groups were not so good. Since then Francis and his co-workers have experimented with a type of vaccine produced by utilization of the phenomenon of red-cell agglutination by the virus. Virus is absorbed out from allantoic chick fluid with red cells, eluted, and subsequently resuspended in a smaller volume of fluid. These manœuvres result in a considerable separation of virus from foreign protein, and also in a concentration of virus antigen. Preliminary studies of the efficacy of the vaccine were made by exposing vaccinated individuals to an immunity test with inhalation of atomized virus A of a recently recovered strain (Francis, Salk, Pearson, and Brown, 1944). This strain was not identical serologically with the strain used for preparing the vaccine. It was found that the vaccinated individuals had a lessened febrile response to the infection, and that the effect of the vaccine was most evident two weeks after inoculation and had practically worn off four months later. The test of infection was presumably severe in that 80% of unvaccinated men exposed to a similar inhalation developed fever and 50% had temperatures over 100°.

The vaccine, which contained equal amounts of virus A and virus B, was given a large-scale field trial in 1943 during the virus A outbreak of that year. The report by members of the Commission on Influenza of the United States Army (1944), who undertook the organization of the trial, contained unequivocal evidence of the value of the vaccine under the particular conditions of the test. The percentage incidence of clinical influenza in the various groups of the 6,000 controls varied from 3.38 to 9.06, that for the groups of 6,000 vaccinated individuals from 1.15 to 5.25. The incidence of clinical attacks in the vaccinated groups was lowered on the whole to one-fourth that in the controls, and only two groups had small differences between incidence in vaccinated and that in control individuals. These figures included all cases of clinical influenza and excluded afebrile colds, follicular tonsillitis, and infectious mononucleosis. Though the result of serological analysis of the influenza cases has not yet been reported, the general prevalence of virus A during the outbreak suggests that the majority of cases belonged to influenza A. It also seemed that immunization did not begin to affect incidence—that is, to confer immunity—until at least eight days after the vaccine was given. One point is of great importance in assessing the result of this trial. Immunization was carried out in October and November with one subcutaneous dose, and the outbreaks of influenza began about the middle of November. In at least one area vaccination was begun after the epidemic was in progress, but in general an interval of two to four weeks ensued between vaccination and epidemic. It may well be, therefore, that the extraordinarily successful timing of vaccination, which was in fact a matter of chance, was an important factor in the success of the experiment. The serological response to the vaccine was actually at its peak when the outbreak of influenza occurred. It seems probable that this question of the time interval between vaccination and exposure to infection by the virus is of critical importance is deciding the effectiveness of the immunization. Not only in the case of our own experience at Shotley, but in the comprehensive trials carried out in State institutions by Muckenfuss and his co-workers in New York State (Siegel *et al.*, 1942), no difference in incidence of cases of influenza in vaccinated or control individuals was seen when the epidemic occurred six weeks or more after the vaccination. That a concentrated type of virus vaccine may still have some significant effect for as long as one year after immunization has, however, been demonstrated recently by Hirst, Rickard, and Friedewald (1944).

All these experiences with human immunization were carried out with influenza A, and much less is known concerning influenza B. Eaton and Martin (1942) showed that formolized allantoic fluid containing virus B was an effective antigen as judged by the production of neutralizing antibodies, and some of us feel that virus B is actually more highly antigenic, at any rate in animals, than virus A. Salk, Pearson, Brown, and Martin (1944) tested their formolized concentrated virus A and B vaccine by exposing vaccinated and untreated individuals to inhalation of active virus B. As in the experiment with virus A, a diminished febrile response was observed in the vaccinated individuals compared with the controls, but a higher degree of residual immunity was discernible four months after vaccination than in the case of virus A. No field trial of an influenza B vaccine has yet been reported.

In Australia the work of Burnet and his colleagues upon the production of immunity by the intranasal use of attenuated virus strains has been pursued since 1937, when it was found that prolonged cultivation of a virus A strain (Melbourne) on the chorio-allantoic membrane of the chick resulted in loss of pathogenicity for the ferret and mouse. At the same time the virus, though causing an inapparent infection of the ferret, produced an antibody response in this animal, and it thus seemed possible that the same result would be obtained in man. The work with attenuated strains both of virus A and of virus B given by nasal spray was summarized by Burnet in 1943. The essential difficulty has been to produce strains with the correct level of attenuation for man. If attenuation is carried too far, as in the case of the original Melbourne strain, the virus produces neither clinical nor serological reaction. If attenuation is not carried far enough, clinical reactions follow. Ideally attenuated virus produces good serological responses which are closely correlated with the pre-existing antibody levels to the virus and which occur in about 20 to 30% of individuals. At the same time, clinical reactions are trivial or absent in the majority, and take the form of coryza, slight headache, or malaise in the remainder. This method of immunization was tested by Bull and Burnet (1943) by determining the response to a second spraying some months after an initial inoculation. Virus B was used, and the experiment has already been referred to. Although, by the criterion of antibody response, the sprayed individuals were mostly immune three to six months later, nasal symptoms were actually more frequent after the second spraying, which suggested that such symptoms may have an allergic foundation. Repeated sprayings carried out by Mawson and Swan (1943) with mixtures of attenuated A and B strains further showed that failure to respond by antibody rise to a first inoculation was again noted after a second spraying, thus suggesting that individual factors in resistance to infection are the cause of the failure to respond in the first place. In the experience of these workers and in that of Burnet and Foley (1940), use of a less attenuated virus strain in such individuals led to actual clinical attacks.

The effect of administration of attenuated virus strains during an actual epidemic was seen in only one unit in 1942. There, though influenza, presumably due to virus A, was actually spreading in the camps, no serious acute reaction followed such as would have suggested that spread from person to person under conditions meteorologically suitable for an epidemic would permit the attenuated virus to regain virulence. Nor, however, was much benefit conferred by the immunization, though the study was not carried out under ideal conditions. A reduction in incidence of influenza from 6.63% in the controls to 4.4% in the immunized individuals was, however, observed (Burnet, 1943). Only further experience will enable full judgment to be passed on the relative merit of this method of immunization compared with the subcutaneous method, but simplicity of production and economy of material make rapid large-scale production of the attenuated vaccine much easier than in the case of the concentrated vaccines needed for subcutaneous immunization. It is also conceivable that the time lag before immunity becomes effective is shorter with intranasal than with subcutaneous vaccines, and therefore in the presence of an outbreak the value of an intranasal vaccine would not necessarily be impaired.

Passive Immunization

I can here do no more than mention the experiments which have been made to confer resistance to influenza by passive immunization of man with serum. Earlier in this lecture I mentioned the use of immune serum intranasally in mice and ferrets, and in man successful use of atomized intranasal serum has been reported from Russia (Smorodintseff, Gulanoff, and Chalkina, 1940). Trial of this method last year by Andrewes and Glover (unpublished experiments) during the virus A outbreak gave inconclusive results because none of the groups in which the method was applied developed a sufficient number of cases of influenza in the non-serum-treated controls after the application of serum to the remainder. It was therefore impossible to draw any conclusions as to the value of the method. Possibly such a method might be of greater value during a pandemic type of influenza with high incidence of pulmonary infection by the virus.

Control of Epidemic Influenza

Rational control of any infectious disease depends on knowledge of the whole cycle of the infection, including the source of the causative agent, its mode of spread, and the factors which underlie natural resistance of the host. In the case of influenza, knowledge is still lacking on many of these points, and particularly on the source of infection and whereabouts of the virus in interepidemic times. Possible methods of control based on the mode of spread have, however, been studied, particularly since the outbreak of war. Andrewes and Glover in 1941 defined the mode of spread of contagion in the case of ferrets infected with virus A and showed that, though distant contagion by fine air-borne droplets was entirely possible, the relatively coarse droplets spread from the mouth and nose, particularly in sneezing, were also of great importance in conveying infection. Human contagion is almost certainly conveyed by true air-borne spread at times, but direct droplet infection from man to man must be important. Dust infection is also possible, as shown by the experiments of Edward (1941) on the resistance of influenza virus to slow drying at room temperatures. The great developments which have taken place in recent years in methods of sterilization of the air were reviewed by Andrewes in 1940 and Stuart Mudd more recently (1944). Air-borne particles of influenza virus have been shown to be capable of destruction by such methods as ultra-violet irradiation (Wells and Brown, 1936), or by germicidal mists or vapours such as hypochlorous acid gas (Edward and Lidwell, 1943) or propylene glycol (Henle and Zellat, 1941). Stokes and Henle (1942) have used propylene glycol vapour in a ward, and have demonstrated that atomized influenza virus released into the air is thereby destroyed.

All these methods may play a definite part in the reduction of air-borne infection in crowded messrooms, air-raid shelters, and places of entertainment. They would inevitably be less successful against the direct spread of coarse droplets over short distances, and, though the wearing of masks would provide ideal barriers against such droplets, experience has shown that people will not readily tolerate such measures. The limitations of physical and chemical methods of introducing barriers to the spread of virus during outbreaks of influenza are therefore considerable. Not much more than a reduction of incidence in particular groups where overcrowding would produce an abnormally high rate can be hoped for so far as the uncomplicated virus infection is concerned. There seems more hope that complications may be reduced in incidence, and in pandemic influenza the value of methods of aerial hygiene would be most definite. I do not propose to elaborate this type of work further, as I have not myself taken part in it. I would, however, point out the fact that, even without special apparatus or knowledge, simple measures of hygiene such as improvement in window ventilation, spacing out of beds, and encouragement of a hygienic attitude towards coughing and sneezing may do much to lower the incidence of infection in disciplined communities such as Army units.

When we turn to survey the problem of control of influenza in general it is obvious that the usefulness of all prophylactic methods is dependent on the particular variety of influenza which it is desired to control. In regard to the type of influenza experienced in recent years, there would be little room for methods which failed to reduce actual incidence though they affected severity or incidence of secondary complication. In the face of an outbreak of influenza of the 1918 type, however, any method which modified the course of infection, even if it failed to prevent it completely, would be of use. Naturally, also, there is, in wartime, increased scope for control measures against influenza in order to effect a reduction in the loss of labour to industry or of time to duty from minor as well as major sickness, and measures which fall short of perfection would be relatively more acceptable now than in times of peace. We have seen the promise held out by methods of artificial immunization in limiting the incidence of infection during an outbreak, and the problem would seem essentially to be the application of the method. In such a periodic disease as influenza we are enormously handicapped by lack of knowledge as to when to expect epidemics. The fact that the methods available for artificial immunization are probably effective for only short periods after inoculation adds further difficulty. It will clearly be useless to immunize unless there is a reasonable probability of an outbreak within the next few weeks or unless the outbreak has already begun in neighbouring areas. Use of a vaccine after an epidemic has begun may not be actually harmful, but, in view of the delay before subcutaneous vaccine exerts an effect, only intranasal virus would then have much chance of success. If we are lucky enough to experience indicator outbreaks during the months preceding an epidemic, as occurred in 1943, then we may be able to apply immunization with benefit, but unfortunately we do not yet know whether such experience is exceptional or not. Should we desist from attempts at immunization because of the argument that we owe our present freedom from a recurrence of pandemic influenza of the worst variety to the regular recurrences of the type of mild influenza which we have been considering? My own view coincides with that of Stuart Mudd (1944), who believes that the dissemination of agents of respiratory disease should be attacked whole-heartedly by all possible methods. On the other hand, there is clearly much room for improvement both in how best to apply vaccines and in their actual composition. An example of possible future developments lies in the recent discovery of Friedewald (1944) that the addition of certain substances—of which a mixture of liquid paraffin, killed human tubercle bacilli, and a lanolin-like absorption base known as falba was the most effective—has an amazing adjuvant effect on the antigenic power of influenza virus, and increases the size and duration of the antibody response to virus given subcutaneously. The application of the methods of aerial sanitation in addition to immunization will certainly be necessary if ever we are faced by a recurrence of pandemic

fluenza of the 1918 type ; and there is the undoubted possi-
lity, as already mentioned, that the causative organism of
ch influenza may be entirely different in type or in anti-
nicity from the viruses so far studied. Faced by a virus
entirely novel antigenic type, it is unlikely that any of our
esent vaccines would have any beneficial effect at all, and
e should probably have to spend our time studying the new
gent in the laboratory during the period when it was wreaking
s vengeance on ourselves and our fellows. General methods
f hygiene as well as the methods of aerial disinfection would
our only prophylactic weapons. The use of quarantine for
land communities, as in Australia in 1918, may only postpone
e fatal day when the pandemic virus begins to spread among
e population ; but such postponement, in addition to allowing
ne for the development of specific methods of attack in the
boratory, might mean that the virus then would be less
rulent than if it reached the area at the height of its passage
rough the population elsewhere.

Conclusion

To summarize: the development of knowledge concerning
e mechanism of immunity and of resistance to influenza virus
fection has been traced in experimental animals and in man.
animals and in man immunity is found to be a complex
ocess, in which the production of antibodies plays only a
rt. Other processes, though less well outlined, belong to
e innate resistance of the mucosa of the respiratory tract,
hich appears to possess methods of defence by virtue of the
sal secretion in addition to more definitely cellular activities.
ossible ways of producing immunity in animals and in man
ve been described, and the general problem of control of
fluenza, particularly by the use of the methods of aerial
erilization, have been mentioned.

No speaker on the subject of influenza has any right to
onclude a review such as I have attempted without once again
nphasizing the fact that we are so fundamentally ignorant
f many of the vital links in the chain of the natural infection
at the need for more research on this aspect is still pressing,
d must occupy as much of our time as methods of application
knowledge so far gained, or even more.

The Empire Rheumatism Council was established eight years ago to organize research throughout the British Empire into the causes and means of treatment of rheumatic disease. The annual report for 1944 is signed by the chairman, Lord Horder, who welcomes an intimation from St. James's Palace that the Duke of Gloucester wishes to continue as president during his term as Governor-General of Australia, and that absence over-seas will in no way diminish his Royal Highness's interest in the Council's work. A committee on postgraduate education has been set up, with Sir Adolphe Abrahams as chairman. The report confirms a recent announcement in these columns that the tests so far made with a Russian serum have not justified recommendation of its use; but in view of the high reputation of Soviet medical research the Council proposes, when war conditions permit, to invite the Russian scientist responsible for the treatment to visit this country, or, alternatively, to send a research worker to Moscow to make further investigations. The Council looks forward to great progress in the field of clinical research on rheumatic disease when the establishment of a national chain of treatment centres will enable comprehensive tests under full control conditions to be made for evaluating present means and proposing new means of treatment. The *Annals of the Rheumatic Diseases*, by agreement between the Empire Rheumatism Council and the Council of the British Medical Association, is now published by the B.M.A. at Tavistock Square.

DUODENAL ILEUS IN THE NEWBORN

BY

VICTORIA SMALLPEICE, M.D., M.R.C.P., D.C.H.

Medical Officer, Rycote Park Extension, Children's Department, Radcliffe Infirmary, Oxford

Duodenal obstruction in the newborn may be associated with a complete atresia or with stenosis caused either by narrowing of the bowel wall or by partial obliteration of the lumen by a membrane. It is, however, with duodenal ileus due primarily to external pressure that we are dealing in this paper.

In 1930, and later, Miller and Gage (1930, 1932, 1935a, 1935b) published a series of papers under the headings "Gastromegaly and Chronic Duodenal Ileus in Childhood" and "Chronic Duodenal Ileus in Infancy and Childhood," describing cases of obstruction to the second and third parts of the duodenum. They considered that there were two separate mechanical factors at work in producing ileus: first, a congenital anatomical factor, where a band of mesentery, usually associated with the superior mesenteric artery, was stretched across in front of the duodenum, causing some degree of compression; and, secondly, the vicious circle likely to be set up by this. They showed how the proximal duodenum tended to become distended and how this, in turn, caused ptosis and kinking over the band, so making the ileus more severe. They stressed the great importance of the latter factor in the causation of symptoms, and showed that if it could be overcome by medical treatment the baby would thrive even though the anatomical factor remained.

Ladd and Gross (1941) gave an excellent description of a further group of cases together with a bibliography. In this group, volvulus of the midgut was superimposed upon a high intestinal obstruction caused by external pressure on the duodenum. They gave a clear description of the embryological basis for the condition. Between the 6th and the 10th week of foetal life the intestinal tract grows more rapidly than the abdominal cavity, and the midgut passes out into the base of the umbilical cord. When, later, the relative rate of growth changes once more, the gut returns to the abdomen and, in the process, it rotates. It follows that the caecum at one stage comes to lie high up on the left and only later passes across to the right upper abdomen and finally to its adult position. When the process is complete the caecum has its peritoneal attachment in the right iliac fossa, while the small intestine is anchored by a diagonal attachment on the posterior abdominal wall extending from the duodenojejunal junction above to the caecum below. The normal process may become arrested at any stage. If the caecum has not reached its final position it may lie across the duodenum, high up and to the right, so that its peritoneal attachment may cause duodenal obstruction. Associated with this, the fixation of the small intestine is likely to be abnormal and volvulus of the mobile midgut may occur.

Symptoms and Signs

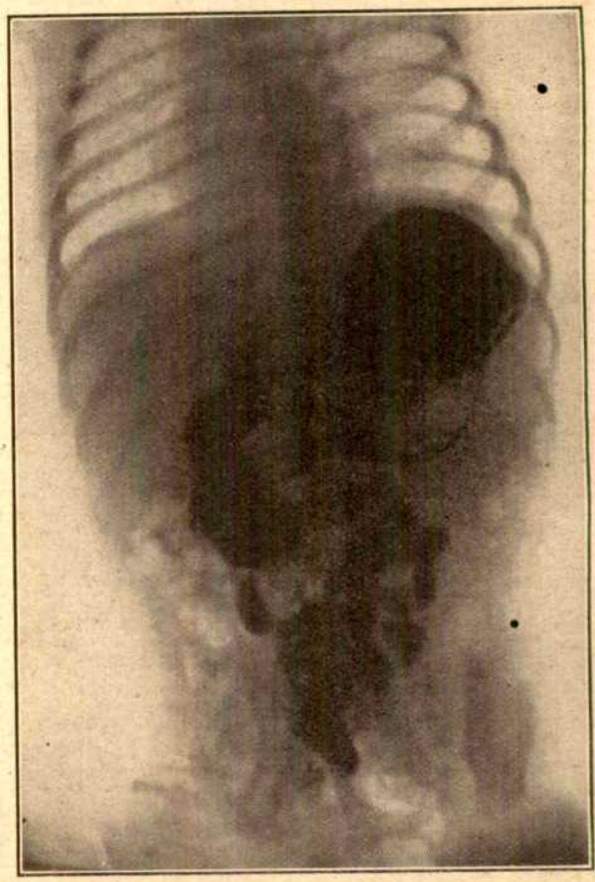
Vomiting is usually the predominant symptom in any form of duodenal obstruction; it is generally forcible, occurring immediately after each feed, and the vomit is often bile-stained. When present this last sign is of great value in diagnosis. Miller and Gage have noted the fact that anorexia is usually pronounced and that if the baby is not forced to take more than it wants its intake is so small that duodenal distension and the onset of vomiting may be delayed. Constipation may be very severe owing to starvation, but the stools, when passed, show no evidence of digestive upset. In the first days of life, when the differential diagnosis from duodenal atresia may be difficult, the identification of cornified epithelium in the meconium may be a valuable finding, proving that obstruction to ingested material has not been complete. Wasting and dehydration vary in degree according to the severity of the case. Distension is limited to the upper abdomen in simple cases; when it becomes more severe the complication of volvulus is to be feared. Visible peristalsis of the stomach may be seen, though not as marked as in pyloric stenosis; duodenal peristalsis, passing downwards on the right, has also been noted.

On palpation of the abdomen, failure to find the characteristi firm pyloric tumour is an important point in the differentia diagnosis between duodenal ileus and pyloric stenosis, thoug it is possible to mistake the duodenum, if distended and fille with curd, for the pylorus. The general examination of th baby includes inspection of the limbs and fontanelle in search for any evidence of a cerebral cause for vomiting, an also the elimination of any possibility of parenteral infectio in the ears, urine, chest, and elsewhere. A straight x-ray fil may be sufficient to show fluid levels in both stomach an duodenum, together with gross distension of the latter. Lad and Gross give a warning against barium meals in these cases as they believe that the barium may become inspissated. Wit care there should be very little danger, and the results ma be of great value in diagnosis.

Case I

First seen Dec. 31, 1940, at the age of 3 weeks. A first child born 2 weeks before term after a normal labour, the baby ha appeared healthy at birth and had weighed 7 lb. 12 oz. Vomitin started "directly the milk came in," usually occurring immediatel each feed had been taken, though it might be delayed for an hour The vomit was greenish yellow in colour, and "sometimes he seeme to pump up more than he had taken." Constipation was severe the baby had had only 4 stools during the 3 weeks of life, and had followed soap enemata. There was nothing relevant in th family history.

On examination the baby was very thin, weighing 1 lb. 4½ oz. les than its birth weight. In spite of this the general condition wa reasonably good, and the infant looked starved rather than ill; ther was no gross dehydration. Seen at a feed, there was no visib peristalsis, though slight distension was observed in the uppe abdomen; no tumour was palpable and the hernial orifices we normal. There was no evidence of disease elsewhere. In view c the history of persistent forcible vomiting of bile-stained flui associated with severe constipation a partial obstruction could b visualized, situated distal to the entrance of the common bile du but at a point high up in the intestine, since there was no generaliz distension. A tentative diagnosis was made of duodenal ileus d to compression of the third part by mesentery.



Barium-meal examination of Case I. Radiograph showing dilatation of the first and second parts of the duodenum.

Treatment.—The baby was admitted to hospital. After gastric lavage a barium meal (see Fig.) was given; the report read: "Oesophagus normal. Stomach normal in situation. Emptying occurred readily. The first and second parts of the duodenum are grossly dilated. There is vigorous peristalsis in this area. The site of the obstruction is at the junction of the descending and ascending portions. The obstruction is only partial and may settle down." The aim of medical treatment was to empty the stomach and duodenum completely twice a day so as to enable them to regain their tone and prevent the vicious circle produced by distension and kinking. With the same end in view, feeds were small and frequent. Gastric lavage was continued twice daily for the first week; the intervals were then gradually increased till a clear result was obtained after four days without treatment. Feeds at first were given at 2-hourly intervals, with 10 feeds in the 24 hours; the intervals were then increased to 2½ hours on the 3rd day and 3 hours on the 9th day. By the 16th day the infant was able to take 3 oz. every 3 hours. On this treatment vomiting ceased almost at once and there was only very occasional sickness after the first 24 hours. The bowels moved normally on the 2nd day and caused no further trouble. There was an improvement in weight, and the baby gained steadily. He was discharged after 24 days in hospital, having gained 25 oz. and being free of all symptoms.

Barium Meal, Jan. 15, 1941.—"Repeat examination. Stomach emptied quite well. There was no hold-up in the duodenum. Stenosis can still be recognized, however."

The child was seen again on Nov. 7, 1944, at the age of 3 years and 11 months. He was well developed and in excellent health. He had been free from symptoms since leaving hospital. A barium meal showed no abnormality of the stomach or duodenum.

Case II

This patient was first seen on Dec. 10 at the age of 15 days. He was a first child, born at full term after a rapid normal labour: birth weight 7 lb. 10 oz. He appeared normal at birth. Vomiting began directly feeds were taken, and persisted for 3 days, occurring after practically every feed. The vomiting had then ceased suddenly and completely, and for the 5 subsequent days the baby took well from the breast and gained weight. Sickness returned on the 8th day and was very severe; it was frequently projectile and the fluid was usually bile-stained. The family doctor had seen peristalsis and palpated a tumour. There had been no bowel action for 4 days. Since the return of the sickness the breast milk had been expressed and given at half strength. The family history showed nothing relevant.

On examination the baby's weight was 6 lb. 9¼ oz. He was thin, but, considering the history, the general condition was fairly good and dehydration was only of moderate degree. Seen at a feed, there was some distension in the upper abdomen, but no peristalsis was visible and no tumour could be palpated. A projectile bile-stained vomit occurred immediately after the feed. Except for slight umbilical discharge nothing abnormal was found elsewhere, and a normal stool was passed. Consideration of the history and physical signs suggested that we were dealing with a case similar to the one already described, and the same provisional diagnosis was made. The obvious difference between the two cases lay in the fact that in Case II there had been one complete spontaneous remission between the 3rd and 8th days of life. Mother and baby were admitted to hospital. In view of the fact that the family doctor had seen peristalsis and palpated a tumour, eumydrine was given for 36 hours, although it was felt that bile-stained vomit should rule out the possibility of pyloric stenosis. The drug had no influence on the vomiting, and was discontinued. In spite of treatment on the same lines as Case I there was no improvement. The baby was therefore put into the Trendelenburg position and the duodenum aspirated with a Ryle's tube; continuous duodenal drainage was kept up for some hours and subsequently repeated at frequent intervals. Additional fluid was given by the subcutaneous route and by continuous rectal drip; half-strength saline, followed by tap-water and glucose, was absorbed extremely well from the rectum. Since there was no fault in digestion and the baby took well, the caloric value of the feed was increased by the addition of 1 dr. of half-cream dried milk powder to each 4 oz. of breast milk. After a day of this treatment the baby for more than 24 hours did not vomit and the bowels opened normally. Unfortunately the sickness returned and persisted with far greater intensity in spite of continued treatment, so that the infant went downhill rapidly and died 2½ days later, 8 days after admission to hospital.

When the vomiting returned, after the short interval of freedom, the question arose whether laparotomy was advisable. Various factors had to be considered. The infant was in poor condition; there had been two remissions, and a third might possibly occur. Looking back, in view of the post-mortem findings (see below) it is just possible that surgery might have been successful even two days before death. We can only make a conjecture as to the sequence of events inside the abdomen. It seems probable that the partial obstruction had been caused in the first place by pressure on the duodenum, either from malposition of the caecum or from the primitive mesentery around the superior mesenteric artery. Then, with the onset of continuous sickness 2½ days before death, a volvulus of the midgut had been superimposed. The volvulus might easily have been relieved surgically, and Ladd and Gross describe a simple operative procedure by which they free the caecum from its attachment high up on the right and allow it to fall across to the left of the abdomen, in which position it can no longer obstruct the duodenum.

Post-mortem Report.—The relevant extract from the report reads as follows: "The body of a small, rather wasted male infant. The head appeared rather large, the fontanelles were a little depressed. The skin was loose. The upper part of the abdomen was somewhat full, though the lower part was insunken. . . . *Abdomen:*—Peritoneal cavity: The stomach was rather large and distended. The duodenum was grossly distended, being almost as large as the stomach. The distension stopped abruptly at about the mid-point of the third part of the duodenum. At this point the duodenum was involved in a volvulus which had occurred at the root of a primitive mesentery around the superior mesenteric artery. The volvulus was left-handed. It was not so tight as to have interfered with the blood supply of the small gut, though tight enough to have prevented the passage of intestinal contents beyond the point of volvulus. The descending and transverse colons were in the normal situation, but the caecum lay on the anterior aspect of the immensely distended second part of the duodenum. The long appendix passed medially over the distended third part of the duodenum. The absence of the caecum from the right iliac fossa, and the drawing up of the small intestine by the volvulus, accounted for the fallen appearance of the lower abdomen. There were no further abnormalities in the abdominal cavity." The body was otherwise natural except for a very few pericardial haemorrhages and a fairly severe tear of the upper leaf of the tentorium on the left, which had healed over, though there was some extravasation of blood into the substance of the tentorium.

Summary

Two cases of duodenal obstruction in the newborn are described. They illustrate two types of case. The first resembled those described by Miller and Gage and responded rapidly to medical treatment. The second probably began in a somewhat similar way, but volvulus was superimposed and caused the infant's death.

I am indebted to Dr. Robb-Smith, Director of Pathology, Radcliffe Infirmary, Oxford, for the post-mortem report, and to Dr. Kemp, radiologist to the hospital, for the *x*-ray reports and the print.

BURNS AND THEIR TREATMENT AMONG E.M.S. HOSPITAL IN-PATIENTS

BY

EILEEN M. BROOKE, M.Sc.

E.M.S. Statistical Branch, Norcross

Examination of the records of the E.M.S. Statistical Branch at Norcross shows that of the total injuries for which Service patients were admitted to the E.M.S. hospitals, burns caused among men about 3% in 1942 and 4% in 1943, and among women about 10% in each year (Stocks and Brooke, 1944). At Norcross every fifth record of admission for in-patient treatment is selected, and the primary, secondary, and complicating causes of admission are coded by means of the Medical Research Council's Classification of Diseases and Injuries. In the code numbering for burns the third digit indicates the agent causing the disability and the fourth digit the part of the body affected. A random sample of 400 of the cases admitted on account of burns during 1943 and the first half of 1944 has been examined in detail, and an analysis of the distribution according to age and site is given in Table I.

Six males and one female died—a proportion of 1.75%. Five deaths of men were due to extensive burns caused by aeroplane crashes. In each case the patient was very shocked

and, despite blood or plasma transfusions and such other treatment as it was possible to give, four died on the day of admission to hospital, and the fifth four days later. The death of a woman was due to toxaemia. Five men and one woman were discharged from the Services as a result of their injuries, after periods of treatment ranging from 162 to 378 days.

TABLE II.—*Distribution of Burns according to Agent*

M.R.C. Code No.	Agent	Males		Females	
		Frequency	%	Frequency	%

13.5% to incendiary bombs and other instruments of war, and 18.9% to miscellaneous agents. Phosphorus caused 10.75% of all burns (included in No. 935–).

Tables III and IV show the distribution and the median number of days of treatment of burns by site and degree. The period of in-patient treatment given for a burn depends not only on its severity and the site and size of the affected area, but also on whether adequate after-care can be provided at the man's unit, in which case he can be discharged before the injury is completely healed. Since this applies chiefly to cases of long duration, the median number of days' treatment for different degrees and sites provides a better measure for comparison than would a complete tabulation of periods of hospitalization or an arithmetical mean of these periods.

The median is naturally high for numbers 93–5 and 93–7, which are for multiple sites. The high median for 93–4, lower limb or limbs, is partly accounted for by there being 8 third-degree burns in this group as compared with 3 at most in any other.

TABLE III.—*Distribution of Burns according to Site and Degree*

M.R.C. Code No.	Site	Degree									
		Males					Females				
		1st	2nd	3rd	Not Stated	All Types	1st	2nd	3rd	Not Stated	All Types
93–0	Face, head, or neck	13	15	3	22	53	3	3	0	1	7
93–1	Trunk	1	3	1	5	10	0	0	0	0	0

* Including burns for which the degree was not stated.

Summary

A statistical analysis is presented of a random sample of 400 in-patients from the Services admitted to all E.M.S. hospitals during 1943 and the first half of 1944 on account of burns. Distributions according to sex and age of patient, site and degree of burn, and duration of treatment are given; and the method of sampling was such that these may be regarded as representing the average experience in E.M.S. hospitals during the period.

I am indebted to Sir Francis Fraser, Director-General of E.M.S., Sir Claude Frankau, Director of E.M.S. in London and the Home Counties, and Dr. P. Stocks, General Register Office, for their help and suggestions.

REFERENCE

Stocks, P., and Brooke, E. M. (1944). *Mon. Bull. Min. Hlth. and E.P.H.L.S.*, **3**, 216.

R. F. Norris, R. A. Kern, H. P. Schenck, and L. E. Silcox (*U.S. nav. med. Bull.*, 1944, **42**, 518), who report an outbreak of 18 cases of diphtheria in a U.S. naval hospital ship in the Solomon and neighbouring islands, state that the efficiency of antitoxin suggests that there is no fundamental difference between the strain of *C. diphtheriae* in the Tropics and those in the U.S.A. Since diphtheria in the Tropics is a comparatively mild disease, it often goes unrecognized and may be followed by fatal peripheral paralysis.

REATMENT OF THE PATIENT WITH BURNS, WITH REFERENCE TO THE PROFLAVINE POWDER TECHNIQUE

BY

RONALD W. RAVEN, F.R.C.S.

ut.-Col., R.A.M.C.; Officer in Charge of a Surgical Division, C.M.F.

e trend of modern surgical thinking is to focus attention on a stated lesion rather than to take into conception a view the patient as a whole. In certain diseases the actual ion is the outward sign of a complex interplay of patho-ysiological processes affecting the whole organism. The rollary is also true as applied to the effects of injury. e local damaged area calls the same general processes into ion, and it is important to recognize and understand the ctions of the body to injury. It has become commonplace discuss treatment under two headings—general and local— t too often inadequate attention is given to the former. ce the measures instituted in the general treatment often ert a local action, and vice versa, it appears advisable to dify this classification and to consider the patient as a whole. e patient with a major burn must be treated from this point view.

Since the outbreak of the present war the subject of burns s received considerable attention and our knowledge has nsequently been enriched. The division of the local lesion o three degrees instead of the classical six of Dupuytren helpful, but it is pointed out that several days usually elapse fore it is possible to classify a burn, and all three degrees y be represented. The psychological aspect requires atten-n, especially with major burns in exposed parts of the body reassurance and encouragement must be given as regards rring, with disfigurement and dysfunction. In burns of the e an early inquiry with respect to these matters is usually de by the patient. For the relief of pain morphine must given in adequate amounts, and if a quick result is desired should be administered by the intravenous route. Interesting periments have been carried out on the effects of nembutal, d it is reported to reduce the fluid loss of the burned surface. these results are confirmed and applied clinically this drug y be used also as a soporific with a double advantage.

Plasma Loss

This is rapid at onset, and may be severe in amount. rther, the loss of plasma is a continuous process extending er a long period of time in the injured area. As a result, poproteinaemia develops. In the pathogenesis of this con-ion more than one mechanism is operative. There is the s of plasma at the site of injury, and in addition the output nitrogen in the urine is increased. The patient is unable ingest an adequate protein diet during the initial period lowing his injury.

Later there may be damage to the liver as the result of ic absorption, with consequent impairment of function in synthesis of plasma albumin. Acute hypoproteinaemia may velop a few hours after a severe burn, and both its presence d its degree must be rectified and corrected. Chemical alysis of the blood should be carried out and the plasma umin fraction measured. In addition, the haemoglobin rcentage must be determined, together with an enumeration the red blood cells. To rectify this condition plasma nsfusion is required as early as possible and in adequate ount. In severe cases a minimum of 1,000 c.cm. is given once, and quickly in rate. Further quantities may be neces-y over a period of time, and the clinical condition of the ient is the simplest guide. Fluid-balance charts must be tituted and the output of urine watched carefully. When the tient is able to ingest it, he should be put on a high-protein t containing a large proportion of essential amino-acids. r an adult of average size 150 g. of proteins per day can given, the best foods being milk, lean meats, and eggs. nino-acids may be given orally if there are digestive dis-bances, but this is an expensive method. In an excellent review of this subject Elman and Lischer (1943) call attention to the value of amigen, an enzymic digest of casein and pork pancreas containing amino-acids and a small quantity of polypeptides. Amigen can be administered orally and intravenously; as much as 300 g. has been given in 24 hours by the latter route. A high protein intake is necessary to safeguard the live cells from the effects of toxic absorption.

Sulphonamide Therapy

It is not our practice to give sulphonamide drugs orally as a routine. In cases of severe toxic absorption and liver insufficiency they may be harmful. Each patient must be carefully considered from this angle and the general condition assessed. Oral chemotherapy is beneficial in cases of haemolytic streptococcal infection with marked pyrexia. An adequate fluid intake is necessary and the response of the patient should be carefully noted. We have ceased to employ these drugs locally in the injured area.

After a period of three or four days secondary anaemia frequently develops, and becomes marked unless measures are taken to combat it. Iron therapy, using massive doses, is instituted. In severe burns one or more blood transfusions may be required during the second and third weeks, and it is our practice to transfuse when the haemoglobin falls below 70%. Hypovitaminosis is corrected by the daily administration of vitamins B and C. Careful attention to the cardiac and respiratory systems is necessary, especially in elderly patients, and cardiac failure or pulmonary infection is treated along routine lines. In the case of septic burns constant scrutiny of the condition of the heart, liver, and kidneys is essential.

In countries where malaria is endemic this infection may be a complicating factor in cases of burns. We have shown elsewhere that trauma may precipitate an attack of malaria in a patient whose disease is quiescent. Thus in patients who are pyrexial in malarious areas it is a wise precaution to examine the blood for malaria parasites on several occasions.

Treatment of the Wound

Wound treatment is carried out under strictly aseptic conditions in the operating theatre, usually without general anaesthesia; morphine should be administered subcutaneously half an hour before the operation, and in severe cases this can be given intravenously with good effect. The toilet of the wound is careful and conservative. Contaminants are mopped away with a solution of normal saline, and pieces of dead tissue are lifted off. Normal skin surrounding the wound is carefully cleansed with spirit. Blisters are evacuated carefully by pricking with a sterile needle. Dry proflavine powder is lightly smeared over the wound, the whole lesion being thinly coated. The wound area is covered with one layer of wide-meshed gauze impregnated with vaseline and, over this, two layers of wide-meshed gauze with a liberal supply of cotton-wool. The dressing is bandaged firmly to form a pressure-dressing with either plaster-of-Paris or calico bandages, and this initial dressing is not removed for a minimum period of five days. After the first re-dressing the time-interval between dressings is increased from 10 to 14 days. Proflavine powder is dusted on the wound at each re-dressing. The wounds in burns of third degree should be skin-grafted as soon as they are in a satisfactory state.

Use of Plaster-of-Paris

We have with advantage used plaster coverings for the dressing in certain parts of the body. Attention is called to the value of the "plaster glove" for the treatment of burns of the hand. The toilet is carried out as described, each finger being covered separately with vaselined gauze and dry gauze. The following technique is employed for the application of the "plaster glove."

The patient is instructed to place the hand in the position of rest, the fingers being partially flexed at the interphalangeal and metacarpo-phalangeal joints, with the tips of the index finger and thumb in opposition. The wrist-joint is held in partial dorsiflexion. A rolled pad of cotton-wool is placed in the palm of the hand as a support for the fingers, and the hand and forearm are covered with a liberal supply of that material. The hand, wrist, and forearm are then encased completely in the plaster glove, which extends as high as a point two inches below the elbow-joint. The limb is elevated for several days in order to minimize tissue oedema. Active exercises are instituted for the fingers after 48 hours, together with active exercises at the elbow- and shoulder-joints.

In the case of burns of the foot a similar technique is employed. The glove is left in position for a period of two to three weeks. Other regions of the body have been treated by the proflavine-plaster technique, including the leg, thigh, forearm, arm, shoulder, chest wall, and abdominal wall. In the case of large joints such as the knee and elbow, bandages are applied, with plaster above and below, in order that active exercises may be carried out. There are several advantages in the plaster technique. The dressing is comfortable and is held firmly in position. If evacuation of the patient is necessary, travelling in plaster is comfortable. In tropical and subtropical countries, where flies are numerous, the plaster forms a barrier against maggot infestation.

In order to illustrate the results obtained reference is made to the following typical cases among those we have treated by the powder. It is our practice to investigate the bacterial flora present in the wound from its inception until healing occurs. On account of the necessity for evacuation it was not possible to hold every patient until healing was established. Nevertheless we have investigated sufficient cases treated by this method to be very impressed with the end-results.

Illustrative Cases

Case 1.—Trooper aged 30 Admitted with major burns—second and third degrees—involving face, neck, forearms, hands, right chest wall, anterior abdominal wall lower half, penis, scrotum, right buttock, and both thighs. Treated with proflavine powder as described. Plasma transfusion 1,350 c.cm. Bacteriology of burns showed coliform organisms. Four days after admission, plasma transfusion 1,350 c.cm. Seven days later re-dressed. Coliform organisms present. He was re-dressed at intervals, and bacteriological examinations showed *B. proteus*, *Staph. aureus*, and coliform organisms. Thirty-six days after the first treatment the wounds were clean, sloughs had separated, and healthy granulation tissue had formed. All areas not healed were skin-grafted, using split-thickness grafts. There was a good "take," and in 69 days the patient was evacuated in good general condition, walking well, and all wounds had healed save a small patch on the right thigh which was in process of healing.

Case 2.—Fireman aged 38. Admitted with major burns—second and third degrees—involving both lower extremities, buttocks, penis, and lower part of the back. The patient had been treated at another hospital, the injury having occurred 18 days before we saw him. He had received sulphathiazole orally, 45 g., and sulphanilamide powder locally. His general condition was very poor and secondary anaemia was present—Hb 68%. Two pints of blood were transfused and routine proflavine treatment given for the burns, which were very infected. A second blood transfusion, one pint, was given 12 days later and again on the 47th day. Dressings were changed at intervals, and bacteriological investigations showed *B. proteus*, *Staph. aureus*, coliforms, and diphtheroids. Patient was evacuated 67 days after admission in good general condition, walking well, and with wounds healed.

Comment

It is of interest to compare Cases 1 and 2, as these burns were of comparable severity. In Case 1, treated with proflavine powder, the general condition did not show the marked toxicity of Case 2, and no blood transfusions were required as in the latter. The lengths of stay in hospital before healing was achieved were 69 and 67 days respectively. The haemolytic streptococcus was absent in all cases, and we believe that such infection can be prevented by the use of this method. Bacteria met with in our cases were *Staph. aureus* and *albus*, *B. proteus*, coliforms, diphtheroids, and *B. pyocyaneus*. In the past it has been stated that the acridine compounds retard the healing process in a wound. This has not been our experience using powdered proflavine in burns and also in other types of wounds. On the contrary, healing is usually rapid and there is a noticeable absence of scarring, the resulting skin being supple and of excellent quality. The hands we have treated are functioning normally and no contractions have developed. It is recognized that a burn of the hand may be of such severity that a deformity will result no matter what treatment is given. There has been no instance of a deleterious general effect from absorption of proflavine at the wound surface.

Summary

In the treatment of burns the patient as a whole must be carefu considered, and the salient features in his management are h discussed. Powdered proflavine has been used in the treatment the wound and the results achieved are described. This chemi substance is of proved value, and we employ it as a routine. Att tion is called to the use of plaster-of-Paris as a covering for dressings, and in particular to the "plaster glove" in burns of hand. Proflavine powder does not retard the process of heali and the resulting healed area showed a remarkable freedom fr scarring, the skin being supple and of excellent quality.

I am indebted to Major T. Day, R.A.M.C., for carrying bacteriological examinations on a large series of patients. C W. A. Y. Knight, A.M.S., commanding the hospital, has kin allowed me to publish the case histories.

Medical Memoranda

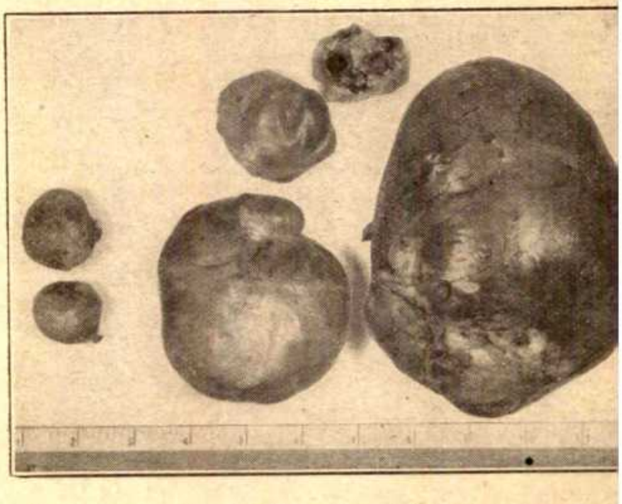
Enucleation of Six Ovarian Dermoid Cysts fro one Woman, with Conservation of the Ovarie

The following case record illustrates the scope of conservat surgery on the ovaries.

CASE HISTORY

Miss J., aged 21 (No. 24703). During a routine examinat a swelling was found in this girl's abdomen. At the West Lond Hospital a provisional diagnosis of ovarian cyst was made, and name was placed on their waiting list. As a result of the air ra in London in the early months of 1944 she came to Oxford was admitted to the Radcliffe Infirmary. On the previous diagno with which I had no reason to disagree, the abdomen was open The operative details are as follows:

Left lower paramedian incision. A bluish cystic swelling aris from the left ovary was immediately apparent; it was about 9 long, and had the appearance of a multilocular ovarian cyst an extension running up towards the left. The uterus was nor in size and position. The right ovary was about 5 in. long, clearly contained two separate cysts, one at each pole. Each in the right ovary was a little smaller than a golf ball, and yellowish in colour, as if filled with sebaceous material such as commonly present in dermoid cysts.



These two cysts in the right ovary were both enucleated ea and bloodlessly, and the ovary was repaired. Because of the fi ings in the right ovary the loculated swelling of the left ovary re-examined. Though each locule was obviously filled with wat fluid, there were in addition a few fat globules to be seen throu the capsule. On the supposition that the left-sided cyst was als dermoid, enucleation was proceeded with. Surprisingly, the turned out to be not one but four quite separate ovarian dermoi Three were enucleated without difficulty, though one was accident punctured; the fourth was removed along with a piece of thinn out ovary. The ovary was repaired and the abdomen closed.

Convalescence was uninterrupted. Before operation the pati menstruated every two months; subsequently she reported her peri as "regular every month."

All six cysts contained hair. The two on the right side w largely filled with sebaceous material; the four on the left with watery fluid. Histological examination confirmed the clini diagnosis of benign cystic ovarian dermoids; a great variety of tis elements were identified.

COMMENT

)ermoid cysts of the ovaries are not infrequently bilateral, it is especially important that the scope of conservative gery should be realized. Furthermore, they often occur in ıng women who have their child-bearing future ahead. ucleation of such cysts is the operation of choice in young men. The operation is easy, tidy, and surprisingly blood-;. I have found diathermy helpful in stopping any slight ting from the tumour bed.

3onney (1937) has recorded cases similar to the above, and ; emphasized that there are many ovarian conditions which, a general rule, should be treated by conservative surgery.

Estimation of Bromide in Body Fluids

e necessity may arise at intervals to check the administration bromides or their mixtures to patients during a course of atment. Particularly is this the case in a mental hospital. suitable and easily worked process would therefore be an vantage, and the one described below is by no means comcated and gives fair results.

Not much work has been undertaken on this subject recently. ıly one process for blood bromide could be found. This s by Barbour, Pilkington, and Sargant (*British Medical ırnal*, 1936, **2**, 957). When testing this method in the hosal laboratory very poor results were obtained, although ndard bromide solutions were employed. It was found that ces of serum protein unprecipitated from the first stage preıted the formation of the gold colour-combine. Further, lium chloride in concentration equal to that obtained in ıod serum similarly prevented the colour formation. Iodides 'e exactly the same colour-combine as bromides when treated h the gold chloride solution.

t will thus be seen that these distracting features had to be ninated before any reliance could be placed upon the results. e following process was therefore instituted.

1. URINE

\ 24-hour sample of urine is collected and measured. 100 c.cm. urine is evaporated to dryness in a silica basin on a water-bath. : urine is previously made slightly alkaline with 5% NaOH. ite slowly until all organic matter is decomposed, but do not tinue heating to drive off all the carbon. Cool, and add about c.cm. of distilled water and a few drops of 5% HCl till slightly l; heat to almost boiling-point and filter. Wash with warm illed water at least three times. Keep bulk of fluid as low as sible, if necessary by further evaporation. Transfer filtrate to a arator and cool. Add 10 c.cm. of chloroform ($CHCl_3$) and 5 c.cm. freshly prepared chlorine water, shake vigorously, and allow Cl_3 + Br to settle for a few minutes. Run the $CHCl_3$ layer into ther separator under 10 c.cm. of distilled water. Treat the ginal solution with a little more $CHCl_3$, shake, and add to first Cl_3 extract. Wash quickly with distilled water. Run the total Cl_3 + Br extract into a separator, add 10 c.cm. distilled water, slowly add just enough anhydrous Na_2CO_3, shaking the while l the red colour of the bromine in the chloroform disappears the whole becomes water-clear. Shake well and allow to settle. aqueous layer now contains NaBr in solution. Run off the Cl_3 carefully. To the aqueous layer 1.5 c.cm. of a 1% gold ıride ($H.AuCl_4$) solution is now added, and drop by drop 5% HCl l the orange-red colour is fully formed. Three or four drops he acid solution should suffice. This colour is then compared ı colorimeter with a standard NaBr solution of known strength ɔr 4 mg.). The appropriate quantity of standard should be ted to the same volume as the final aqueous solution of the erial under test, made slightly acid with dilute HCl, and 1.5 c.cm. he gold solution added.

est of Process.—4 mg. of NaBr was added to 50 c.cm. of a nal urine and the entire process carried out. 3.81 mg. of NaBr recovered. Tests on patients receiving exact quantities of nide daily showed an excretion of from 60 to 70% of the added over that period.

2. BLOOD

he process can be adapted to blood, a small measured quantity which is incinerated slowly until most of the carbon is driven off. ther steps are then completed as above. It is most advisable : to keep the bulk of the liquid as low as possible. The results ' vary slightly owing to the small amount of sample used.

t is not claimed that this process is 100% efficient, but with :ful working comparative results will be assured. The chemireactions made use of are of the simplest nature and, should e desired, the test could be carried out in any laboratory.

ffordshire Mental Hospital, Stafford. J. S. SHARPE. M.B., Ch.B.

Gaucher's Disease: Diagnosis by Sternal Puncture

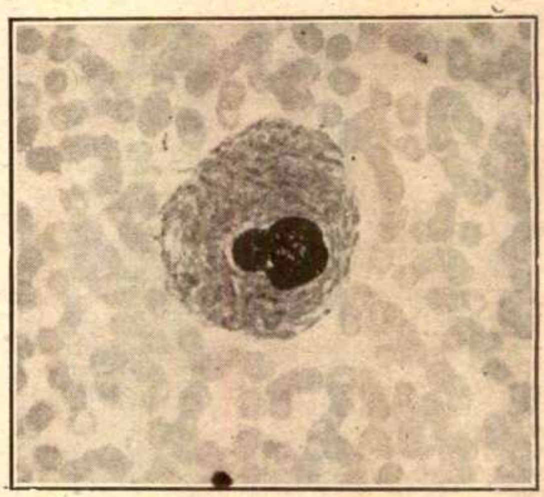
The case reported below was referred to me by the Armed Forces Medical Board on account of splenomegaly. The diagnosis of Gaucher's disease was made by sternal puncture. In view of the rarity of the condition and the fact that this case was revealed by the routine examination of recruits it is felt that a brief clinical memorandum would be of interest.

CASE HISTORY

The patient, a youth aged 19, is of British nationality and is not of Jewish ancestry. There is no familial history of splenomegaly. One brother died at birth. The father is at present on active service in the Royal Navy. The mother is alive and well, and apparently healthy. He has had no serious illness apart from an attack of bronchitis at the age of 10, though there have been occasional mild attacks of "influenza." During these attacks the patient feels a creaking sensation over the spleen.

Eighteen months ago the spleen was found to be enlarged when he was examined by his doctor during an attack of "influenza." Since then an increase in the size of the spleen has been noted. His general health is good and he has played rugby and water-polo without difficulty.

Examination revealed a tall, well-built youth of healthy appearance, with no conjunctival pingueculae or abnormal pigmentation. There was no abnormality of the nasopharynx or chest. The blood pressure was 130/85 mm. Hg. The spleen was enormously enlarged, with a firm edge and an easily palpable notch. In the supine position, at a point 2 in. lateral to the umbilicus the lower margin of the spleen was 6 in. from the costal margin. The lower thorax on the left side was visibly bulged forward by the underlying spleen. The liver was not palpable. There were no palpable glands apart from a few small slippery glands in the left axilla.



Investigations.—Blood count:—Hb 110% (Haldane scale); mean diameter of cells (halo method), 6.8 μ; red cells, 6,120,000 per c.mm.; leucocytes, 6,000 per c.mm.—polymorphs 56%, lymphocytes 40%, monocytes 4%; platelets, 285,600 per c.mm.; red cells stain normally. Bleeding and coagulation times were normal. Urine:—No protein of any nature present. Hippuric acid excretion test for liver function:—In one hour 17.4%, in two hours 47.5%, in four hours 82.6% of ingested sodium benzoate excreted. Red cell fragility to saline normal. Radiographs of skull, scapula, humerus, pelvis, and lower ends of femora showed no abnormality. Marrow smear:—After a prolonged search a typical Gaucher cell was found (see photomicrograph). Otherwise the picture was within normal limits.

Emanuel (1941) reported two cases of Gaucher's disease diagnosed by sternal puncture. In one, that of a man aged 30, the splenomegaly was revealed through the routine examination of recruits.

I am indebted to Prof. S. L. Baker and Dr. C. E. Jenkins for their interest and help, and to Mr. Gooding for his excellent photomicrograph.

M. L. THOMSON, M.D., M.R.C.P.,
Honorary Assistant Physician, Salford Royal Hospital.

Emanuel, E. (1941). *Edinb. med. J.*, **48**, 843.

There were 25,285 persons on the register of the Pharmaceutical Society of Great Britain at the end of last year, compared with 25,224 the year before. The total includes 4,471 persons known to be serving with H.M. Forces. Since 1900 the number of pharmacists has increased by 10,000 and is now 1 to 1,800 of the population, compared with 1 to 2,700 in 1900. The proportion of women pharmacists is now 10.5%. Last year the number of women entering pharmacy was 52% of the total.

Reviews

BACKACHE AND SCIATICA

Backache and Sciatic Neuritis. Back Injuries, Deformities, Diseases, Disabilities. With Notes on the Pelvis, Neck, and Brachial Neuritis. By Philip Lewin, M.D., F.A.C.S. With drawings by Harold Laufman, M.D. (Pp. 745; 235 figures. 50s.) London: Henry Kimpton.

This work has been written for the general practitioner. To many the anatomy and mechanics, the investigation, diagnosis, and treatment of the spine when deranged or diseased is a closed book. And yet an enormous literature has been accumulated upon different aspects of these matters. It is a notorious playground of the charlatan. That an attempt should be made by such a distinguished orthopaedist as Dr. Lewin to "open this book" is timely. Yet he would have been more successful if he had been disciplined by even a little of the shortage of paper with which our medical writers have to contend. If "brevity is the soul of wit," so also conciseness and clarity are the essence of science.

Though well printed and illustrated on good paper it is very uneven in its teaching. There are some excellent chapters, particularly on the investigation of spinal disturbances and upon general matters of treatment. The whole is tinged with a naivety which will be somewhat strange to crusty old conservatives of Great Britain, and yet is often stimulating to those who understand American ways of thought and humour. Nevertheless the volume is clouded to a disturbing extent by verbose repetition. The work of other writers is freely quoted but often with lack of critical assessment and explanation such as the general practitioner really needs. An impressive bibliography is added as an appendix, but to a number of the items there mentioned we find no reference in the text, and, conversely, we found authorities noted in the text and no corresponding entry in the bibliography. The book seems to have been written in haste, with no proper editing, for how else could one have such repetitions as on page 439, where it is stated:

> "Pure sciatic neuritis is rare. It probably does not occur except . . . due to metallic poisoning, arsenic or lead, or to an infection or as alcoholic or syphilitic neuritis, as an avitaminosis or from anaemia. Sciatica may be due to diabetes, syphilis, alcoholism, lead poisoning, or any lesion producing an inflammatory or degenerative change directly in the nerve tissue." . . . "The predisposing factors in sciatic pain are congenital anomalies, postural defects and metabolic, circulatory, and endocrine disturbances. Determining factors are infection, trauma, exposure, and fatigue. Any focus of infection, exposure, etc., may precipitate an attack. Vitamin deficiency is also a predisposing factor."

This is not an isolated instance. It is also found, for example, on page 442 in an involved discussion upon the relation of the pyriformis muscle to the sciatic nerve. A section on page 471 on "Uncontrollable Brachial Neuritis" is entirely concerned with a proposal of Cushing's for the treatment of malignant spinal metastases with paralysis below the 12th thoracic segment by transection of the spinal cord. Further on we find, under "Chordotomy," a confused statement of the origin of the Spiller-Frazier operation. Discussing traumatic lesions of the sciatic nerve it is stated: "The order of return of function following *internal popliteal* (tibial) injury is: the gastrocnemius, tibialis posticus, *peronei, tibialis anticus*" (our italics). The last two mentioned muscles are later correctly listed under injuries of the external popliteal nerve; but an equally confusing and inaccurate statement had already been given on the page before.

Into the book has been dragged much material whose relation to backache is slight—e.g., burns and skin grafting, gas gangrene, anaesthetic and general surgical technique—and some irritating repetition in describing and enthusing upon the Kenny treatment of poliomyelitis. The lack of condensation and judgment, the insertion of inconsequential asides, and numerous inaccuracies produce an unfortunate atmosphere of confusion. Such errors shake our confidence in the book as a whole, and this confidence is not increased by reading the detailed and over-enthusiastic description of operations for ruptured intervertebral disks and spondylolisthesis, by inadequate illustrations of the radiological appearances of spinal lesions (e.g., spondylolisthesis), the intrusion of illustratio from the advertising literature of commercial firms, and a me passing reference (and that Putti's) to the use of the plast jacket in sciatica.

After reading the book and going back to Dr. Steindler foreword it seemed to us still true that "even the most arde advocates of surgery concede that backache is largely a proble for conservative treatment. . . . What we still need is to b shown how far rest can be accomplished by conservative mea and when and why operative methods . . . become necessary Dr. Lewin has, we feel, "just missed the boat."

THE CANCER PROBLEM

The Riddle of Cancer. By Charles Oberling, M.D. Translated by William H. Woglom, M.D. (Pp. 196. $3.00 or 20s.) Connecticut: Yale University Press; London: Oxford University Press. 1944.

In 1942 the book *Le Problème du Cancer,* by Prof. Charl Oberling, was published in the series "France Forever," i Montreal. On both sides of the Atlantic experts in canc research recognized that here was a book which provides th balanced and exact information needed by medical studen by doctors who have not enough time and leisure to rea original literature widely, and even by well-informed lay peop It is not primarily a book for those who are well acquaint with cancer literature, but even for the expert it provides ide and novel analogies and subtle arguments which cannot fa to enlighten and broaden his conception of the vast proble which cancer presents.

Cancer research has now become so extended that it almost beyond any one man's capacity to be master of a its branches; such a man would need to be very we acquainted with chemistry, bacteriology, genetics, parasitolog as well as with pathology and general medicine. The mass facts now accumulated about cancer—e.g., the induction cancer by a hundred or more pure chemical compoun administered by feeding or injection or by mere inunction the skin; the initiation of cancer by hormones, the influen of heredity, the action of viruses, the part played by Bittne milk factor in mammary cancer—must necessarily cause co fusion or lead to sterile argumentation unless the whole ma can be surveyed and correlated in a way which does n offend the general sense of the fitness of things. The key the general survey is the pathology of cancer, and he Prof. Oberling is completely at home. He realizes as acute as the early pathologists who disentangled cancer from gran lomas, and the pioneers of cancer research—e.g., Bashfor Leo Loeb, Ehrlich, Borrel—that the problem to be solv is autonomous growth, a form of growth which is unique pathology. Again and again in his discussions of the meani of the many discoveries which have been made during t forty years of experimental cancer research, Oberling us the pathological nature of cancer as the touchstone of impo tance. To review this book adequately would need mo columns than any journal could possibly spare; all aspects the subject are dealt with fully and fairly.

The French edition of this book was attractive not on because of the masterly way in which facts were broug together to form a rational picture of perhaps the mo complicated disease process in the whole realm of patholo but also because of the elegant precision of the langua It must often occur to the English reader that our Fren colleagues have an advantage over us in the language they u But it must be admitted by all readers of Dr. Woglon translation that the English edition loses little or nothing the grace and beauty of the original. Dr. Woglom deserv the thanks of the English-speaking world for giving us su a faithful and beautifully written volume.

TROPICAL MEDICINE

Tropical Medicine. By Sir Leonard Rogers, M.D., F.R.C.P., F.R.S., an Sir John W. D. Megaw, M.B. Fifth edition. Churchill's Empire Series (Pp. 518; illustrated. 21s.) London: J. and A. Churchill. 1944.

That a new edition of this book has been called for with two years of the appearance of the fourth edition is perha not surprising in view of the increasing number of medi officers being drafted for service in the Tropics. The autho as they say, have resisted the temptation to increase the s of the book by the incorporation of new matter. Such fre formation as was necessary, particularly in the chapters voted to malaria, kala-azar, trypanosomiasis, typhus, leprosy, d dietetics, has been introduced by the procedure of rewriting any pages in these sections. The upshot of this has been actual reduction in the size of the book. To the casual server it appears unchanged, but careful inspection shows at much new information of real value has been included, that readers may rest assured that in it they will still find thoroughly reliable and up-to-date account of all those nditions which are grouped under the heading "tropical seases." The book was written originally for the tropical actitioner, and this objective has not been lost sight of; this, the fifth, edition the medical officer who has to deal ith patients in the Tropics will find all the information he eds, not only for treating the sick but also for maintaining health those under his care. As with the earlier editions, e latest can be thoroughly recommended to all those, whether ung and inexperienced or old and mature, who are called on to practise medicine in the Tropics.

Notes on Books

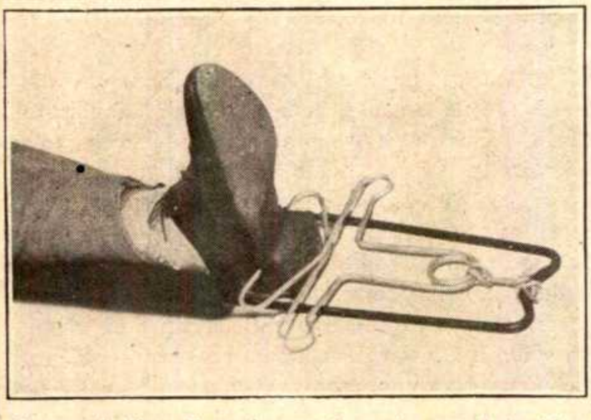
wis's Medical and Scientific Library, Gower Street, London, .C., was founded in 1848 to supply mainly the needs of members the medical profession and also to lend out books of scientific, chnical, or philosophic interest not to be found in the ordinary rculating libraries. It has proved a boon to generations of medical udents and practitioners and to workers in the allied sciences. The st full catalogue (to Dec., 1937) has been out of print for some ne, and a Supplement covering the four-year period 1938 to 1941 also out of print. A new edition has been revised to the end of 43. Part I, "Authors and Titles" (714 pages), and Part II, Classified Index to Subjects with Names of Authors" (208 pages) e issued together in one volume from 136, Gower Street (12s. 6d. to bscribers; 25s. to non-subscribers). Every book in Lewis's Library the latest revised edition, and the aim of the catalogue is to pro- de subscribers with the titles of the works available there. For asons of space and practical usefulness books for which there is demand and textbooks which have passed out of date are with- awn from time to time. The catalogue includes about 24,000 les and it forms a very useful work of reference.

Preparations and Appliances

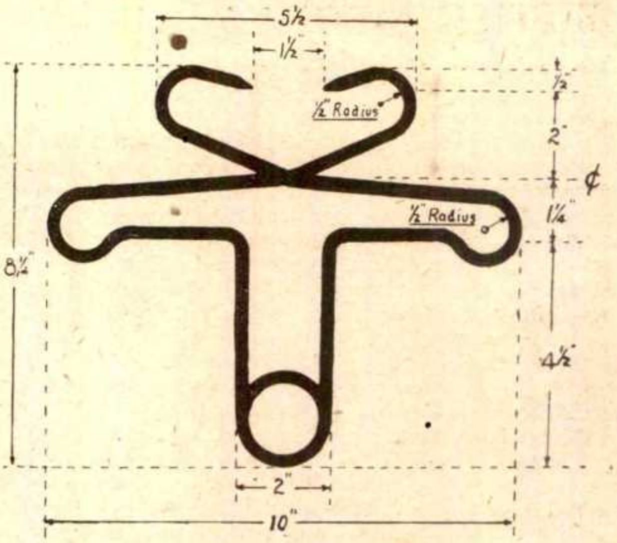
CLIP FOR USE WITH THOMAS SPLINT

r. J. R. M. WHIGHAM, *M.C.*, M.S., F.R.C.S., writes from . Andrew's Hospital, Bow, E.3:

The accompanying illustrations show a clip for use with the omas splint which has proved valuable. It is made of 1/4 in. und mild steel and consists of jaws, wings, and tail. The ws grip the side of the boot, the wings rest on the parallel rs of the splint and prevent rotation, and the tail when htly held opens the jaws ready for application on the principle the towel clip. Extension cord can be attached either to e tail or to the wings. The more the pull on the wings the eater is the grip on the boot.



The grip resembles in some ways the Millbank pattern of eut.-Col. Monro, R.A.M.C., detailed in the *British Medical urnal* (Feb. 10, 1940, p. 217), but the addition of the tail gives the clip a handle and makes it, I think, easier to apply, especially under the difficult conditions which often confront the first-aider. A ready sling for the fractured limb can be improvised by passing the splint through the sleeve of a jacket, and this completes the essential treatment.



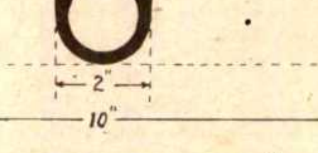
STEADYING GADGET FOR TOCANTINS'S NEEDLE

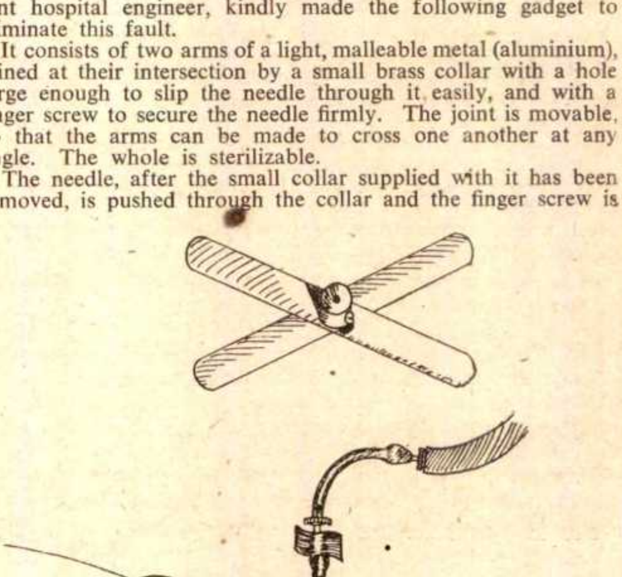
Dr. BRIAN V. I. GREENISH writes from the Grove Hospital (L.C.C.):

When using the longer types of Tocantins's needle for intramedullary drip therapy in the tibiae of infants, especially if treatment has to be continued for longer than 24 hours, the needle tends to become less stable than it is at first, due partly to its own slight top-heaviness, partly to contraction of the child's muscles, and partly, no doubt, to its unavoidable movement when the child has to be changed. On several occasions I have found this to lead to leakage of fluid back through the tissues, escaping where the needle penetrates. Mr. Delo, assistant hospital engineer, kindly made the following gadget to eliminate this fault.

It consists of two arms of a light, malleable metal (aluminium), joined at their intersection by a small brass collar with a hole large enough to slip the needle through it easily, and with a finger screw to secure the needle firmly. The joint is movable, so that the arms can be made to cross one another at any angle. The whole is sterilizable.

The needle, after the small collar supplied with it has been removed, is pushed through the collar and the finger screw is tightened. The arms are straightened and the needle is pushed into the medullary cavity. The arms are then moulded round the child's leg and secured with adhesive plaster. The needle is thus firmly held, the efficiency of treatment is increased, and the child is relieved from the great discomfort of an unsteady needle.





BRITISH MEDICAL JOURNAL.

LONDON

SATURDAY FEBRUARY 24 1945

INFLUENZA: WHERE WE STAND

Scrutiny of the epidemiologist's tables and charts can tell us much about the nature and behaviour of influenza, but vital statistics alone have not revealed and are never likely to reveal the whole story. Nor can we expect that study of the behaviour of influenza viruses in laboratory animals will, by itself, unravel the mysteries of the disease. There is urgent need for concerted attack by epidemiologist, clinician, and laboratory worker. Progress made by such correlated studies is reviewed in the first of Lieut.-Col. Stuart-Harris's Goulstonian lectures, published in our issue of last week. The yearly variations in the incidence of influenza take on a new significance when we know that the major peaks have been associated with the activity of influenza A virus, and that in years without pronounced peaks that virus has been rarely, if ever, isolated. Influenza A virus is now recognized to have been the causative agent of almost every one of the serious outbreaks all over the world since, in 1933, it was shown to be pathogenic for ferrets and thus became amenable to study in the laboratory. The serologically distinct influenza B virus, first recognized in 1940, has been recovered in a few wide outbreaks, sometimes in association with the A virus, but has not been proved to be a major cause of trouble; there is some evidence that it is more apt than is A to cause sporadic infections or to be associated with grumbling outbreaks not showing the sharp peaking which is characteristic of A epidemics. Virus A tends to make itself felt every other year; in this country it seemed liable to cause particularly large outbreaks every fourth winter. Thus it hit us in 1933 and in 1937. It was detected in the blitz winter of 1940–1, but, when we most feared it, the threatened outbreak came to nothing. Its next public appearance was in the winter of 1943–4, when it started a sharp outbreak in October instead of waiting till its favourite month of January. We understand that neither virus has yet been detected this winter.

Certain winters, as in 1934–5, 1938–9, 1939–40, and perhaps this winter also, have no major epidemic, but clinical influenza turns up in larger quantity than in other blank years; sometimes it is most noticeable in semi-closed communities, in outbreaks which do not spread generally. These "intermediate" years are particularly puzzling. Laboratory study shows that virus A may be present, but in a minority of clinical cases, and B may exist alongside it; but most cases are not obviously associated with either virus. Stuart-Harris discusses whether another strain of virus is at work here or whether modified strains of A or B are concerned. Wh virus A is recognized in such seasons it tends to be low virulence for ferrets, and the antibody response attacked persons is also of a lower order than in epidem years.

The second of the Goulstonian lectures, published this issue, deals with experimental evidence as to immuni to influenza and with the possibilities of active immuniz tion. Serological studies of human sera have been carri out on a large scale, especially since Hirst's discovery th influenza virus will agglutinate fowl and other red blo cells. This agglutination is inhibited by specific antiser and this inhibition is the basis of a quantitative test whi can be carried out in any laboratory where fresh blo cells are available. It now seems clear that possession high-titre antibodies does not guarantee anyone again getting an attack of 'flu, for the disease may assault peop having antibodies at any level. There is, however, a te dency—no more—for influenza to lay low in larger nu bers persons with relatively poor antibodies. This bei so, vaccination, which probably acts by raising antibo levels, will never guarantee an individual against infectio though it may appreciably reduce the incidence in a co munity. Virus inactivated by formalin and injected su cutaneously has been the basis of almost all influenza vir vaccines to be tried; these have been improved lately substituting for mouse-lung filtrates allantoic fluid fro infected chick embryos. Such material contains mu more virus and less unwanted protein than preparatio used earlier. Concentration by several methods can applied to improve the product still further. Unfortunate evidence suggests that even the best vaccines have effect on immunity of comparatively short duration, pe haps a couple of months. A recent trial in America, whi Stuart-Harris mentions, gave much the best results recorded—approximately a fourfold reduction in inciden of clinical influenza; but, as he says, "it may well . . . that the extraordinarily successful timing of vaccin tion, which was in fact a matter of chance, was an impo tant factor in the success of the experiment." For in th trial the outbreak began at just about the time when response to the vaccine was at its height. At present, wh we cannot foretell just when an epidemic is coming, would be wasteful, if not actually harmful, to inject infl enza vaccines indiscriminately, on the off-chance of epidemic's appearing when the resulting immunity was st raised. The alternative course, though administrative difficult, seems much wiser at present—namely, to pla laboratory-trained scouts to look out for evidence activity by viruses A and B and to distribute a inject the appropriate vaccine as rapidly as possib when the scouts' reports indicate that the right mome for doing this has come.

A recent report by Friedewald suggests that, by mixtu with suitable adjuvants, an influenza vaccine will produ much better and more prolonged effects: this work has n yet reached the stage of clinical application, but its furth development may ultimately solve some of our difficulti Meanwhile we do well not to look only to vaccines banish influenza from our midst. Far more do we ne learn all the grisly details of the natural history of the irus. The factors permitting epidemics to arise are ertainly complex. One of them is the cyclical variation the immunity of the herd, high after an outbreak, gradu- lly falling till the next one begins. Another concerns the hereabouts of influenza A virus between epidemics. It as but rarely been incriminated as a cause of sporadic ifluenza. Was there any special significance in its appear- nce in scattered local outbreaks in the summer preceding e October–December, 1943, epidemic? Is it ever brought our shores from abroad? Can the virus lie hid in some ther host, as swine influenza has been shown to do in e pig lung-worm and earthworm? If the chain of caus- ion of influenza epidemics proves to have many links e may hope all the more to find one of them which is ot too hard to break.

Stuart-Harris touches but lightly on the crucial but ghly speculative question of the relation between ordinary outbreaks and pandemics such as that of 1918–19. In recent and fascinating review of pandemic influenza ope[1] says: "We may be missing something of signifi- nce in the epidemiology of influenza by placing our entire nfidence in the conception that every case of influenza, pecially at the outset of a pandemic, must of necessity ring from some preceding case of the disease." Discussing e autumn wave of 1918, he points out the difficulty of plaining on the basis of contact infection "its relatively ow diffusion over comparatively short distances as com- red with its unbelievably rapid spread over geographi- lly wider areas." It is gratifying that Stuart-Harris sees signs suggesting that a pandemic visitation is threaten- g the final stages of World War II. We devoutly hope is right.

TREATMENT OF LARYNGEAL CANCER

e treatment of carcinoma of the larynx has fascinated ryngologists and surgeons for some ninety years, since arcia made the living vocal cords visible in the laryngo- ope. In the early days it could not be expected that e disease would often be diagnosed in its initial stages; nsequently any rational treatment by surgery had to adapted to at least moderately advanced cases, but if t radical enough it was naturally disastrous, while if nceived on a scale appropriate to the extent of the dis- se its mutilating character carried the seeds of disaster the magnitude of the plan. Of the many who laboured overcome the technical difficulties Gluck above all others cceeded in converting the story of failure from all kinds septic complications, of which he has given a careful storical account,[2] into one of the most satisfactory apters in the tale of surgery for carcinoma. Without ing further into historical detail it may be said that the olution of laryngeal surgery has now produced a reason- ly safe operative technique appropriate to every stage intrinsic cancer, so long as it remains intrinsic. Laryngofissure, modified hemilaryngectomy, and total laryngectomy (now by the aid of chemotherapy almost freed from risk in otherwise sound subjects) provide a standardized technique applicable to all the varieties of situation and extent of the disease, and it is unlikely that much further technical progress will be made in this direction. The less mutilating of these procedures, suitable for early cases, provides nearly 80% of cases free from recurrence for ten years; while total laryngectomy in more advanced cases, where the cancer is not only more extensive but often changing in character to a more malignant type, provides 60% of ten-year cures.[3] Nevertheless it is only natural that, for an organ so intimately connected with the functions of voice and respiration and deglutition, efforts should be made to cure the disease by radiotherapy without subjecting the patient to the hazards and mutilation associated with surgery. If these efforts are to be justified, however, they must show results at least as good as may be claimed for excision. The direct application of radium to the growth, or as near as possible to the base of the tumour, was the method first adopted, and with various modifications it still finds favour in the practice of some who like to combine surgery with radiation; but radiation applied from a distance in the form of deep *x*-ray therapy or by beam from a large quantity of radium has also been given extensive trial and with some measure of success.

Using radium needles applied to the base of the growth by removal of part of the laryngeal cartilages Harmer[4] reports that of 24 early cases 14 survived three years, and of 72 more advanced 32 patients are still living. This gives percentages of 58 and 46, which are inferior to the results of surgery. Lederman and Mayneord[5] in a study of the distribution of radiation from teleradium in the larynx by different techniques showed by physical measurements how these techniques can be adapted to individual needs, while when radium needles are used as the source of radiation the distribution in the horizontal plane shows a region of heavy irradiation principally at the anterior commissure but falling off rapidly along the cord towards the arytenoid cartilage. Morton, Gray, and Leary[6] have also found, by measurement of the dosage reaching the area of the vocal cord and its environment, that by the usual method of employing needles the anterior part of the larynx receives twice the dosage that reaches the posterior part. Therefore, unless the tumour is very small, complicated methods of application are needed to ensure a homogeneous dose throughout a tumour which has extended much either along or below the vocal cord, and homogeneity of dosage is one of the guiding principles for this form of radiotherapy. It may be that a method of applying needles in conformity with this principle will be devised, but the method generally adopted hitherto gives one reason why treatment with needles so often fails except in very early cases where the growth is small. In any event there is no means of telling beforehand whether an epithelioma will prove to be radio-sensitive or radio-resistant, but for needling a rigid standardized technique must be applied. It might be expected, therefore, that high-voltage deep *x*-ray therapy or treatment by teleradium would have certain advantages, both in the matter of distribution of the dosage throughout the volume of tissue to be irradiated and in enabling the treatment to be adapted to the progress of the case by observing the local reaction to the radiation. In fact both Nielsen and Strandberg[7] (Copenhagen) and Max Cutler[8] (Chicago) have gone so far as to recommend a therapeutic test in order to discover whether the tumour is radio-sensitive, in which case a full course of treatment is administered, or whether it is radio-resistant, so that if the response is unsatisfactory the case may be transferred to the surgeon. This assumes, however, that the radiotherapist will have the moral courage to abandon his line of treatment in midstream, as it were, and such an Olympian level of reasoned pessimism is not to be expected of every radiotherapist. However, Lederman[9] can show by the use of teleradium the following results at the Royal Cancer Hospital: out of 8 early cases 6 remain free of symptoms, and of the other two patients, who also became free of symptoms, one died from intercurrent disease and the other is untraced; out of 15 more advanced cases (i.e., suitable for laryngectomy) 12 patients are living and free from symptoms, 6 of them for more than five years. This appears to indicate a clear superiority over treatment by needles, though the figures are still small.

The position at present therefore remains that surgery can give as good results for laryngeal cancer as for any other situation favourable for surgery. Not only is biopsy useful surgically in confirmation of the diagnosis, but Broder's grading provides a fair indication of the degree of malignancy and therefore of prognosis from the surgical standpoint, though at present histology gives no information on the matter of radio-sensitivity. If a surgical line of treatment is chosen much attention must be devoted to selection of the appropriate operation. There should be no exploratory laryngofissures. If the choice of treatment falls upon radiotherapy—which may often claim an advantage in the case of the aged and of those who nowadays are described, regardless of grammar, as "poor surgical risks"—then a decision has to be made between (*a*) the local application of needles, with economy of radium but erratic dosage and some risk of wound infection, and (*b*) irradiation at a distance by deep *x*-ray therapy or by teleradium, with accurately distributed dosage, absence of operative risk, and the opportunity for observing the progress of the case during treatments. It is useless to deny that the introduction of radiotherapy has enveloped the whole subject in a fog of prejudice and bias; and the best that can be done for any individual patient is to place him in the care of someone who has had a comprehensive experience of both lines of treatment and is capable of deciding what is the best treatment for the particular case, or in the care of a surgeon and a radiotherapist who are really willing to co-operate.

PRECOCIOUS FEMALE PUBERTY

If every physician were first to say to himself: "It depend what you mean by 'precocious,'" many an infant bell would remain unscarred. That there is a great variatio in the time of onset of puberty among perfectly health girls is obvious. It is not so obvious at what stage it justifiable to believe that the onset is early or late enoug to warrant a search for a cause. Climate and race a certainly factors to be considered. Puberty at 9 is unusu in Northern European peoples, but would certainly n be considered abnormal in southern or tropical race Are we justified in regarding as deviations from healt even such extreme cases as that of Lina Medina, th Peruvian girl who began to menstruate at 7½ months an created a world's record by giving birth to a child whe only 5 years and 8 months old?[1]

The constitutional element is one which has been ne lected by many workers. The onset of puberty depend so far as present knowledge goes, on two factors—the pr duction of oestradiol by the ovary, presumably as a resu of pituitary stimulation, and the response of the tissue to this ovarian hormone. That the latter factor is variabl not only between individual and individual but betwee one part and another of the body of an individual, an even between the right and left sides of the individual, well recognized. It seems impossible to escape the co clusion that the response of a girl's tissues to oestrogen stimulation is, as Novak[2] has put it, part of "an unde lying foreordained sex pattern innate in the huma mechanism and having its source in the chromosom themselves." If this is so we must expect to find wi variations in the age of onset of puberty in the absen of any discoverable endocrine cause. A disorder of th endocrine system may be expected sometimes to cause a abnormality in time or in strength of the necessary oestr genic stimulus, but it cannot affect the underlying suscept bility to stimulation of the tissues of the body. In fact, tumour as a cause of precocious puberty is rightly su pected but seldom found. A tumour of the adrenals, whic may cause precocious puberty in boys or virilism in girl is a very rare cause of true female puberty. Reilly an his colleagues[3] were able to find only 4 reported case Pineal tumours, on which great stress was formerly lai produce true precocious puberty only in boys, and it now accepted that they do so not by virtue of any end crine overactivity but by pressure upon the hypothalamu Lesions in this area, tumours of the tuber cinereum an corpora mammillaria, hydrocephalus, and encephalit have been occasionally reported as causing true fema precocious puberty, probably by interfering with th functional control of the anterior pituitary. Of great numerical importance is the granulosa-celled ovari tumour. Lull[4] was, however, able to collect only reported cases of precocious puberty due to this caus Even so, the patients are not strictly pubertal, for the "menstruation" is in reality oestrogen-withdrawal blee ing, and ovulation is lacking.

In a recent review Novak[2] has emphasized the rari of neoplastic cases (one in 60,000 patients passing throug the department of gynaecology of Johns Hopkins in 6 years), and has emphasized the relative frequency of th constitutional type hitherto neglected by the majority workers. How common such cases are it is impossib to say, for different observers have used different criter of precocity, and many cases have doubtless gone u reported or have been reported without full investigatio

[4] *Amer. J. Obste .Gynec.*, 1941, **41**, 445.

As an index it is noteworthy that Novak has never encountered a neoplastic case in his own practice, but here reports 9 cases, 6 of them his own, in which the investigation and subsequent history make a constitutional diagnosis inevitable. The age of the first menstruation in this series varied between 15 months and 7½ years, the arbitrary age at which children were excluded from the series being 8.

The prognosis of the constitutional type of precocity is good. The girls grow into normal adults, except for a tendency to stunting of the long bones due to early union of the epiphyses. Their psychological management may be difficult, and it must be remembered that they ovulate and may, like the young girl of Peru, become pregnant.

EMOTIONAL ALBUMINURIA

Like the systolic heart murmur, albuminuria is a call for critical attention rather than a sign of disease. Benign albuminuria, which occurs in the absence of organic renal disease, is a well-known condition which is quite common in adolescents and young adults. It is frequently orthostatic, the albuminuria being associated only with the erect posture. It also occurs in almost everyone after violent exercise, and is not uncommon in students before examinations and in other conditions of mental strain. The factor of emotion in the production of benign albuminuria has recently been given prominence by Ahronheim's observations[1] on a large group of men between the ages of 17 and 26 years who were potential air cadets in the United States Air Corps. The routine procedure included the examination in each case of two specimens of urine obtained within a period of 15 minutes, the second specimen being voided after the routine withdrawal of blood for a Kahn test. Albuminuria was present in practically all " fainters "— those who either fainted or showed shock-like symptoms and felt sick. In the whole group more than 50% showed albuminuria, of which the majority had a positive reaction only in the second specimen. A detailed follow-up was not possible, but it was calculated that the albuminuria was persistent in only about 2%. Ahronheim showed that there was a direct relation between emotion and the occurrence of the albuminuria, and he made the rather comforting if indefinite observation that in 50% of an unspecified number a considerable albuminuria cleared promptly when the subjects were given a draught of medicine which had the properties of being bright and bitter.

In considering the pathogenesis of emotional albuminuria a clue is provided by the very high incidence in the " fainters," in whom there were the usual signs and symptoms which document gross vasomotor disturbance. It is known that in animals even transitory interference with the arterial or venous supply to the kidney produces albuminuria.[2] In the orthostatic type the alteration in posture probably produces albuminuria as the result of a transient renal circulatory disturbance. It is therefore not difficult to accept as a likely factor in emotional albuminuria a transient change in the blood flow of a similar nature, an effect of the widespread vasomotor disturbance associated with syncope. Although the translation of the psychic disturbance into terms of vasomotor changes is probably mediated through the hypothalamus, there is no reason to suppose that a close parallel exists between emotional albuminuria and the so-called cerebral albuminuria of acute brain injury. Acceptance of the view that benign albuminuria is common carries with it the assumption that the glomerular capillary membrane is often permeable to plasma protein under conditions which are within the range of experience of the normal individual and the normal kidney. The facility with which protein can pass through the glomerular capillary wall is in keeping with the trend of recent work by Whipple[3] and others,[4, 5] which suggests that there is a much freer and more rapid passage of protein between the circulating plasma and the protein stores of the tissues than is suggested by the orthodox view that the capillary wall is relatively impermeable to plasma protein.

PROBLEMS OF INANITION

The study of inanition is one of great interest to both clinician and physiologist. In certain medical and surgical conditions lesions in the intestinal tract often interfere with the digestion and absorption of food, and some degree of inanition results. If this goes on long enough the patient may die. To some extent life can be prolonged by parenteral feeding with glucose, amino acids, vitamins, and emulsified fats, although such therapy is still experimental; the only substances in routine use are sodium chloride, glucose, and blood products such as plasma. We still do not know enough of the nutritional requirements in inanition. Holt and Kajdi[6] have thrown some light on the subject by noting the survival times of rats fed on water and single foodstuffs only. Rats have an uncanny skill in making dietetically sound selection of food. When offered a variety of pure foods they choose those suitable not only for optimal growth but for optimal calorie intake as well. Holt and Kajdi therefore assumed that in inanition the rat will eat only what it can make use of, and that its survival will indicate its need for particular foods made available to it. Survival was longest on a protein diet. Rats fed on fat or carbohydrate alone showed a gradual loss of appetite beginning towards the end of the first week and continuing progressively until death. This was attributed to lack of some dietary factor or factors concerned in the utilization of fat and carbohydrate. Rats fed exclusively on fat, carbohydrate, and protein diets drank widely varying quantities of water, the most with protein and the least with fat. The greater need for water on a pure protein diet is explained by the increased quantity of urea formed; it must have water for its excretion.[7] The " water-sparing " property of carbohydrates and fats is of some practical importance, particularly in conditions in which the intake of water is restricted either for therapeutic reasons or because of actual scarcity. Pronounced variations in survival rates were also observed with different carbohydrates. The best results were obtained with glucose, fructose, maltose, cane sugar, and invert sugar, which were almost identical in effect. On pentoses, lactose, and galactose survival rates were lower.

The gradual failure of appetite in rats given carbohydrate and fat to eat was attributed to an impairment of the utilization of food. In further experiments Holt and Kajdi[8] showed that deficiencies of the fat-soluble vitamins and minerals played no part in the phenomenon. Vitamin B_1 deficiency developed regularly in the third week of the tests, but there was no evidence of a deficiency of any other factor of the vitamin B complex. The most serious—namely, a deficiency causing failure of appetite on the third or fourth day—is apparently the want of some factor needed for making use of carbohydrate and fat. At present its nature is unknown. It may be some undiscovered food factor, or the protein component of some enzyme, which cannot be synthesized when the diet is lacking in protein.

THE PROPHYLAXIS OF TRENCH FOOT

BY

RAYMOND GREENE, D.M., M.R.C.P.

Physician, Emergency Medical Service

In every war in history trench foot has been a serious cause of casualties. In the last great war there were 84,670 such casualties in the British Army. In the week ending Dec. 16, 1916, there were 3,104 cases in France and Flanders alone. One blizzard in November, 1915, caused 15,900 cases in Gallipoli and 988 in Serbia. After 1916 the incidence fell rapidly. It was realized that trench foot is almost completely preventable.

The present spell of mild weather following a hard frost is ideal for the production of this malady, and the time seems appropriate for a summary of the teaching which has been given to a large number of medical officers of the three Services in the war medicine courses at the British Postgraduate Medical School of the University of London.

Given proper training and good equipment, the incidence of trench foot is an index of discipline. It is the army in retreat, low in morale and with its communications in disorder, that suffers most severely. In other circumstances, it is almost as foolish to get trench foot as to blow off one's big toe with a rifle. There are bound to be unexpected circumstances in war to make the occasional case unavoidable, but when once an epidemic has been controlled every case should be the subject of inquiry. Almost every such inquiry will bring to light an error in training, equipment, or discipline which, checked in time, will save not merely sections or platoons but even brigades and divisions.

There is a way of life in cold damp weather which must be learned not only by medical officers but by combatant officers and by every individual man. The maintenance of cold-weather discipline must be the responsibility of the combatant officers, but it is the duty of the medical officer to see to it that his brother officers understand the reasons for the rules, and are continuously alert for breaches of them. In the battle against cold there is no place for "toughness." The man who breaks the rules and gets away with it is not a hero but a lucky fool. Moreover, he is a stumbling-block to those who are less well adapted, and he should be treated as a criminal.

Preliminary Training

In the training of troops it should be remembered that the physiological reactions to cold, which are the concern of the adrenal medullae, the thyroid, and the autonomic nervous system, are themselves capable of being trained. In those habitually overclad they become dulled. Troops should accustom themselves to exercise for short periods in the minimum of clothing in the coldest weather. In safe surroundings no more clothing should ever be worn than is necessary to prevent shivering. It is probably not necessary to emulate the Finnish custom of "wallowing naked in December snows," but bathing in cold water and drill in frosty weather stripped to the waist are both of great value.

Clothing

Sir Thomas Lewis showed that if the whole body is chilled the local protective reactions against cold may fail. The clothing must be as nearly as possible waterproof, for it is the great thermal conductivity of water which is to blame for trench foot. It should also be windproof, so that the protective warm layer of air about the body is not too often blown away. The clothing should be in many light layers rather than a few heavy ones, for the air caught in the interstices is of more value than much wool.

All clothing must be loose, for the essential cause of tissue damage in trench foot is the exudation from damaged capillaries, and the slightest venous constriction raises the intracapillary pressure to a serious degree. For this reason puttees were discarded. The boots must be loose, supple, well oiled, and preferably without toecaps. Socks should be undarned, and also loose. Most men can realize that tight boots are dangerous: they forget that tight socks are equally so. They forget, too, that though it is a good thing to wear two pairs of socks if the boots are large enough to take them, it is dangerous if they are not. Ideally the outer pair of socks should be a size larger than the inner, but this is a refinement usually impracticable. Garters and sock suspenders should be forbidden, the socks being kept up by pinning them to the pants. Gloves also must be loose. Some people favour an inner glove of thin silk covered by a woollen one, with a big outer glove of waterproof material. Personally I have always found an ordinary woollen glove perfectly satisfactory and the silk one unnecessary. The outer waterproof glove is important. It should be made without separate fingers and should be loose enough to slip on and off easily when fine finger movements are needed.

Damp

Dry extreme cold is far less to be feared than damp slight cold. Trench foot has occurred in temperate climates even in the spring. For this reason it is absolutely necessary that wet clothes, especially boots, socks, and gloves, should be changed at every opportunity. Combatant officers are sometimes inclined to regard such an instruction as "soft": they must be overruled. A general routine order issued to British Armies in France in November, 1915, laid it down that every man should carry a second pair of socks, and that where possible battalion arrangements should be made for socks to be dried and reissued during each tour of duty in the trenches; and that while in the trenches boots and socks should be taken off from time to time if circumstances permitted and the feet dried, well rubbed, and covered with dry socks. Although much more is now known of the pathology of trench foot, it is almost impossible to improve on this general routine order and the later Fourth Army standing order of June, 1917. Obviously the one extra pair should be increased to several whenever possible. Even if the boots cannot be dried, dry socks are a considerable protection.

The provision of gum boots for use in waterlogged trenches is important, but it must be remembered that sweat is itself dangerous, and gum-boots are sweaty things. Men must not march far in them. In the last war it was usually possible to arrange for men going forward for a tour of duty in waterlogged trenches to call at a post where they removed their boots, performed foot drill, and put on dry socks and gum-boots. On their return they left their wet socks and gum-boots, again performed foot drill, and donned their own dry socks and boots before going down the line.

Foot drill was performed in pairs. Each man washed the feet of his opposite number in warm water and carefully dried them. He then, in the early part of the war, rubbed in whale oil, but it was later found that the oil was unnecessary and a powder of talc and camphor was substituted. The benefit of the whale-oil treatment probably rested in the rubbing. All abrasions were reported to the medical officer. A double washing with ordinary and special soap was ordered, but this is probably an unnecessary refinement. A single wash with ordinary soap is probably as good. Foot drill should be performed in cold weather, both in and out of the trenches. A good method of drying boots is to lay a 6-foot length of gas-pipe across a brazier, push one end into the toe of a boot, and blow air from the other end with a bellows. If the business end of the pipe is made like a toasting-fork many pairs can be dried at once. These measures were often regarded as fussy, but the proof of the pudding was in the eating. The incidence of trench foot fell dramatically after the winter of 1915–16.

Stagnation

After constriction the most important cause of increased intracapillary pressure and consequent oedema and tissue damage is venous stagnation. The men must be taught not to stand still, slumped into their boots, but to keep the muscles of their calves continuously in motion. They must lie down whenever possible, with their feet higher than their heads—a manœuvre which lowers venous pressure. They must not sit on seats, boxes, or firesteps in such a way that the popliteal space is constricted. They must on no account bring their feet near to a fire if they are cold or numb, but warm them between a companion's hands or inside his clothes. The boots must be unlaced or, better, removed at every opportunity and at least twice a day.

Food

The warming power even of cold food is considerable, and men in danger of trench foot must be kept well supplied. Hot food is, of course, far better. Arrangements must be made by means of heat-insulated containers, self-heating tins, or such devices as "Tommy's cookers" for a regular supply of hot food and drink to men in exposed situations.

Trenches

The design of trenches in mobile warfare is easy to neglect, but is neglected at peril in time of thaw. Whenever possible they must be properly drained, or, as a second best, provided with duck-boards. Men cannot stand long periods in damp trenches. Commanding officers may be well aware of this in theory, but they may suffer from a wishful faith in the capacity of their own men to "rough it out." Such faith is always misplaced. Human physiology is remarkably adaptable, but it is not infinitely so. No equipment, however good, no precautions, however studious, and no watchfulness, however devoted, will avail if men have to spend more than 24 or at the most 36 hours in a waterlogged trench or fox-hole. If the prosecution of the war demands that men should fight in such conditions, then the High Command must allow for a high proportion of casualties. It is unreasonable that allowance should be made for casualties from firearms and not from the equally predictable hazard of cold. This hazard has not gone with the thaw. It has rather increased and will remain with the armies till summer comes.

AVIATION MEDICAL RESEARCH

AIR MARSHAL WHITTINGHAM'S ADDRESS

On Jan. 31 Air Marshal Sir Harold Whittingham, Director-General of the R.A.F. Medical Services, was presented with the John Jeffries Award of the Institute of Aeronautical Sciences of the U.S.A. We print below some extracts from his speech in acknowledgment of this honour.

Liaison across the Atlantic

Early in 1939 I had the privilege and pleasure of visiting the United States to see the high-lights of aviation and its associated researches. I visited 12 States, and was particularly impressed by the fine work done at Wright Field, in Dayton, by Col. (then Capt.) Harry G. Armstrong. I returned to the United Kingdom determined to build up so far as was in my power an aviation medical research organization much on the lines of Wright Field, where the aeronautical engineers and other scientists worked as a team with those engaged in the physiology of flight. The urgent problem was to fit the machine to the man, instead of the other way round, as had so long been the case owing to insufficient co-operation between the engineering and medical groups. That was a defect which this Institute has done much to eradicate.

Since 1939 there has been the closest and happiest liaison between British and American research centres and workers, both Service and civilian, including your National Research Council. To our mutual benefit, members of research groups from both countries have visited each other, and continue to do so, to study and discuss various problems at first hand. Thus on either side of the Atlantic and in the field, America, Britain, and Canada have pooled their knowledge and resources in aviation medicine to improve the comfort and efficiency of those engaged in flying during training and on operations.

Some Problems Investigated

Among the problems investigated, roughly in order of their occurrence, have been the following:

How to provide an adequate supply of oxygen, with the maximum of comfort, at all oxygen-requiring heights under the most adverse conditions.

How to protect air-crew against cold and the occurrence of frost-bite, which has now been reduced to negligible proportions (1 case in 2,000 bomber sorties—that is, 1 case in 12,000 individuals engaged in these sorties) by the provision of suitable clothing, particularly electrically heated garments.

How to prevent blacking out in combat during high acceleration without interfering with pilot-readiness, active movements, and performance under all climatic conditions.

How to guard the eyes against the glare of the sun and searchlights without reducing the field of vision or visual acuity, and how to obtain and maintain the optimum night vision under various flying conditions.

How to deal with such stratosphere problems as the prevention of bends, the physiological requirements in pressure-cabin design and development, including explosive decompression and bailing out from aircraft at altitudes over 30,000 feet.

How to lessen fatigue, which is such a potent factor in the causation of air accidents.

How to improve intercommunication, as poor intercommunication leads to fatigue and many errors, especially during the height of air operations.

How to protect those in cockpits and cabins of aircraft against the possible entry of noxious substances, such as exhaust gases or hydraulic fluids.

How to prevent air-sicknesss, particularly among paratroops.

Evacuation of Casualties by Air

In addition a considerable amount of research and development has taken place in connexion with air-sea rescue, and last but not least the evacuation of casualties by air.

The U.S. Army Air Force has done a stupendous job in evacuating casualties by air from all fronts to oversea bases and to the United States. Major-General David N. Grant, your Air Surgeon, deserves the greatest credit for this wonderful achievement, as he does also for the gigantic strides that your country has made in aviation medicine during this war.

The British endeavour, as regards evacuation of casualties by air, has been less only in proportion to the Forces employed. In 1944 the Royal Air Force alone evacuated approximately 300,000 cases of sick and wounded, mostly Army personnel, on all fronts—the Far East, the Mediterranean, and in Europe proper—without a single mishap, although this evacuation involved some 20,000 separate flights, and much of the flying was done from forward landing strips near the enemy, over jungle, mountain, and sea in all sorts of weather.

Outstanding Pieces of Work

I should now like to pay tribute to certain medical men of both countries who have done outstanding work for aviation. Some of our theoretical calculations of the effects of stratosphere flying on man have proved to be wrong; certain hazards were overstressed, others were underestimated, with resulting casualties.

In 1941, during the experimental phase of adapting the Boeing 17 for operational work at higher altitudes, two R.A.F. medical officers —Squad. Ldrs. W. K. Stewart and J. Robson—had the misfortune to be in one of these aircraft when it broke up at an altitude of some 32,000 feet. Stewart was the sole survivor.

Col. Randy Lovelace, of the U.S. Army Air Force, in 1943, purposely and courageously bailed out at 40,000 feet to make physiological observations in a parachute descent from such an altitude. He became unconscious almost immediately after bailing out and suffered severe frost-bite of the hand, but fortunately landed safely. Only last year another distinguished American research worker, Col. Boynton, met his death doing an experimental delayed parachute drop from 44,000 feet, though he knew the hazards. He was a very brave man and a great loss to science.

Again, Squad. Ldrs. Gibson, Pask, and Stewart carried out a series of dangerous experiments—to find out how long man could live during a parachute descent without additional oxygen—in rarified atmospheres similar to those between altitudes of 44,000 and 25,000 feet. These laboratory experiments were carried to just short of extremes and gave valuable information to help perfect apparatus and technique for bailing out in the stratosphere.

In studying the problems of high acceleration in aircraft, that brilliant young American scientist Lieut.-Cmdr. Lillienkrantz met his death tragically some two years ago.

In the Royal Air Force Squad. Ldrs. W. K. Stewart and S. Davidson have carried out since 1940 many hundreds of blacking-out experiments in the air, having to bail out from damaged aircraft on more than one occasion. Squad. Ldr. Davidson has also for the past year been engaged in experimental flying on jet-propelled aircraft to study various physiological problems. In this connexion it is of interest to note that some 120 R.A.F. medical officers are qualified pilots, many being highly skilled—flying Spitfires and even jet-propelled aircraft.

Many medical officers have made physiological and psychological observations during actual air operations against the enemy to assess the strain, fatigue, behaviour of air-crew, and general efficiency of the flyer and his equipment. Thus, in 1942, that gay, lovable Highlander, Group Capt. Hugh Corner, was shot down in his Spitfire by a Messerschmitt over the English Channel when studying what he called "mental lapses" of members of Paddy Finucane's Fighter Squadron.

Wing Cmdr. Roland Winfield has done some 50 operational sorties to study aviation medicine problems in bomber and coastal aircraft on all fronts. Wing Cmdr. MacGown has won the coveted Pathfinder badge, studying night-vision problems over Berlin and other enemy targets.

To assess the flotation value of life-jackets for the unconscious man Squad. Ldr. E. A. Pask had himself anaesthetized for a total period of 3½ hours, while he was thrown into a swimming bath in different positions, wearing various types of life-jackets. Many of these jackets were so designed as to ensure drowning of an unconscious man. Of the types he tested, the British Mae West, the New Zealand Navy, and the German life-jackets proved to be the most efficient and to give adequate flotation. A film of these tests was shown to all concerned, and most of the defects have now been remedied.

In conclusion, I would like to stress that these advances on aviation medicine have been accomplished only by the full co-operation of aircraft instructors, aeronautical engineers, medical men, physicists, physiologists, and textile experts of the United States of America, Britain, and the Dominions working in the closest liaison. Long may this association for our mutual benefit endure in peace as in war.

ROYAL COLLEGE OF SURGEONS

RESTORATION AND DEVELOPMENT FUND

There must be many Members of the Royal College of Surgeons of England and other medical men and women who are interested in the effort to make the College a still more worthy headquarters of surgery in this country. We therefore reproduce below a personal letter which the President, Sir Alfred Webb-Johnson, Bt., sent on Feb. 14 (John Hunter's birthday) to each of the Fellows of the College, asking for their support for the Restoration and Development Fund.

The President's Appeal

The time has come when we must prepare for the restoration of our College. The sum which will be received from the War Damage Commission will not cover the whole cost of restoration; moreover, we have a unique opportunity to carry out many improvements which will make our College an even more worthy headquarters of British surgery. Among the amenities which it is proposed to provide are a large Conference Hall, common rooms, extensions of the museum and library, accommodation for the new professors, and more research laboratories. It is estimated that £250,000 will be required to complete the scheme of development. In order to have a free hand in planning, and, at the same time, to provide space for the sister colleges if they decide to move to Lincoln's Inn Fields, the Council has acquired several adjoining properties.

The future scientific influence of the College has been assured by the generous endowments we have received from Sir Buckston Browne and the Bernhard Baron Trustees, and from our latest and greatest benefactor, Sir William H. Collins. I now appeal to Fellows of the College for donations to the Restoration and Development Fund. I realize that commitments vary for all of us, and that many of us have suffered considerable financial loss owing to the war, but I want every Fellow to feel that he has made some contribution towards making our College worthy of its progressive outlook and great history and traditions.

Past and present members of the Council and Court of Examiners have subscribed over £10,000. The appeal has been supported by the American College of Surgeons, the Royal College of Surgeons of Edinburgh, the Royal College of Surgeons in Ireland, and many surgical associations. Donations can be earmarked for special purposes and can be spread over a term of years. If a gift is intended for the scientific departments a seven-years covenant can be entered into with the result that the benefit to the College will be greatly increased. I rely on you to help as generously as possible.

R. N. Herson, G. P. Christopoulos, and N. F. Coghill (*J. R.A.M.C.*, 1944, **83**, 107) record their observations on 432 cases of mumps occurring between November, 1942, and the end of April, 1943, principally in Cypriot troops stationed in Cyprus, and representing part of an epidemic in the island at that time.

Reports of Societies

PENICILLIN: USES AND LIMITATIONS

A discussion on the uses and limitations of penicillin took place at the Medical Society of London on Feb. 12. The president, Dr. ANTHONY FEILING, was in the chair.

Sir ALEXANDER FLEMING said that penicillin was received for use as a yellow powder. Pure penicillin was in white crystals; the yellow denoted impurity. With penicillin were administered a number of impurities, the composition of which was not known, and which varied according to the methods of extraction and manufacture. Originally it was said that the sodium salt only could be injected, but with the higher standard of purity of the material which had now been reached this was no longer true; the calcium salt could be used for all purposes, and it had one advantage over the sodium salt in that it was not so deliquescent. One important thing about penicillin was that it was non-toxic to leucocytes. The ordinary antiseptics like carbolic acid killed the leucocytes more quickly than they killed micro-organisms. Penicillin was reputed to be bacteriostatic, but it was being established that it did kill micro-organisms and helped to dissolve them. He showed a table dividing the organisms which were sensitive and insensitive to penicillin:

Sensitive	*Insensitive*
Staphylococcus	B. pyogenes
Streptococcus (except enterococcus)	B. proteus
	B. influenzae
Pneumococcus	B. pertussis
Meningococcus	B. pestis
Gonococcus	V. cholerae
Diphtheria bacillus	Friedländer's bacillus
Anthrax bacillus	Enterococcus
Morax-Axenfeld bacillus	Tubercle bacillus
Gas gangrene bacillus	
Tetanus bacillus	
Spirochaetes	

Penicillin must be brought into contact with the micro-organism. The expensive way, though the easy one, was to inject it so that it got into the blood; the cheaper but more troublesome way was to put it on to the infected area so that it reached the organisms locally. In injecting penicillin into a vein the administration must be repeated because the kidney excreted it very rapidly. With the intravenous method, using the standard dose of 15,000 units, most of the substance had disappeared within an hour. With intramuscular injection it remained for about two hours; if 50,000 units were given, for rather more than four hours, and, if 100,000 units, for rather more than six. Intravenous drip was the most economical method of using penicillin, but it involved certain troubles, while as to intramuscular drip, there was a limit to the amount of fluid which could be put into a muscle with comfort to the patient, but subcutaneous drip served the purpose quite well. The latest apparatus for introducing the requisite small amount of fluid was one in which a small clock or motor worked a spindle in such a manner as to turn a screw once in an hour, and this was connected with the piston of a syringe so that up to one million units, or something like ten times the ordinary dose, could be given subcutaneously in 24 hours without discomfort.* The stock dose of penicillin was 124,000 units in 24 hours given either by single injections or by drip. His clinic had been successfully using half that dose when the ordinary sensitive organisms, like the staphylococcus and the streptococcus, were concerned. With less sensitive organisms the dose had been larger.

Dramatic Effects of Penicillin in Gonorrhoea

The treatment of generalized infection caused by any of the sensitive micro-organisms could be undertaken with success, and when penicillin became plentiful Sir Alexander Fleming had no doubt that this would be done. Cases of staphylococcal septicaemia, which formerly were regarded as almost hopeless, now all but invariably got well. In venereal diseases the effect of penicillin was dramatic. Gonococcal infection seemed the asiest of all to get rid of by means of the drug. The stock reatment at the moment was 100,000 units split up into 8 or 0 doses given at 2- or 3-hourly intervals. This seemed to cure omething like 97% of the cases. Such frequent repetitions ere not administratively so suitable for civilians as for those n the Services, and in the case of civilians the plan was ften followed of giving 100,000 units in the morning and 0,000 at night, and it seemed to serve the purpose, though was probably not as good as the frequently repeated adminis-ation throughout the day. Syphilis was now being placed n the list of diseases to be treated with penicillin. A start as made by giving 120,000 units for a week in the usual plit doses; this had since been doubled, but even with the maller dosage the spirochaetes disappeared in from 12 to 15 ours. The Wassermann reaction became negative, and the atient appeared well, though in some cases there was relapse, nd he was a bold man who would declare that he could cure yphilis with anything.

---

* See *British Medical Journal*, Jan. 27, 1945, p. 122.

Oral and Respiratory Infections

Penicillin was likely to be extremely successful in the region f the mouth and the respiratory tract. Nearly all the micro-rganisms common in these regions were sensitive to peni-illin; the only trouble was to get the penicillin into contact ith them. He did not know how to get penicillin into a nus, but most sinus infections were due to penicillin-sensitive rganisms. He mentioned one case of fractured jaw which was xpected to become septic. Penicillin was given for 4 days. nd the wound healed without sepsis. Penicillin if injected into e blood did get into the meninges, though not in high oncentration.

The two serious limitations of penicillin were its instability nd its rapid excretion. When made up in the form of solu-ons, ointments, creams, or lozenges (he was sure that when it ecame plentiful there would be enormous quantities of peni-illin lozenges used for the less serious mouth infections) it as unstable. If anybody could invent a method whereby it as not rapidly excreted this would simplify the treatment ery greatly. Some would say that it was a further disadvan-ge that it could not be given by the mouth, the acid in e stomach destroying it; that, however, might be an advantage preventing its abuse. Great care had to be exercised in aking it up to see that it was bacteriologically sterile, other-ise something might be produced with it which would destroy e penicillin, and what was administered would not be peni-illin but a culture of the organism which had destroyed it. ut if care were taken over these details there was in peni-llin something nearer to the ideal antiseptic than had ever een known before.

"The Surgeon's Occupation Gone"

Mr. A. **Dickson Wright** said that penicillin was an anti-ptic which went beyond all the dreams of the bacteriologist. the last war Sir Almroth Wright was always looking for an tiseptic which would kill micro-organisms and would not ll the leucocytes, and they now saw how right his quest had en. Here was something which worked in a concentration of in 50 million, which was equivalent to 1 drop in 550 gallons. one sweep all the infections of the skin and all the infec-ns of the airways were almost brushed aside by this one tiseptic. "We are only left now to discover something for e alimentary tract, and then we are through." The sur-on's occupation would be gone. It was true that he might ve still to deal with collections of pus, but in this war, in hich penicillin had been used with great liberality, large col-ctions of pus were not found. Boils and carbuncles had been nply "wafted away." Osteomyelitis, which was a busy field r the surgeons, would presently be closed to them entirely. aemic arthritis and pyaemic infections of the joints would brought to an end. The ear, nose, and throat surgeon would d fewer occasions for his intervention. In urinary condi-ns Mr. Dickson Wright had seen stubborn staphylococcal fections of the urinary tract swept away by penicillin. onderful results had been recorded in the treatment of gonor-oea. Childbirth fever might be expected to disappear. Post-operative infections were nearly always staphylococcal, and the use of penicillin would save many a patient from disappointment and complaint and many a surgeon from chagrin. In orthopaedics large operations on the hip were very prone to develop staphylococcal infections, and these would now be under control. As for dentistry, he imagined that in all future extractions a prophylactic dose of penicillin would be given. In Vincent's angina penicillin gave miraculous results. Within 24 hours the most vicious and firmly entrenched "Vincent's" had all the "kick" taken out of it. He had seen a large carbuncle of the lip, giving the patient acute misery, lose all its venom within 24 hours. So far as virus diseases were concerned, apparently nothing was claimed for penicillin, though he believed it had been used and found of value in psittacosis. When the chemistry had been worked out he felt sure that some method would be found of linking penicillin with a radicle, as had been done with insulin, to delay its absorption. Penicillin had "opened a vista which leaves us reeling." One thing was certain: surgeons were going to lose a great deal of their work, and the people were going to enjoy a tremendous benefit.

Dr. A. **Hope Gosse** said that empyemas had been found to be "penicillin-sensitive." In some cases, if the empyema had been diagnosed quite early before thick pus had formed, the fluid seemed to clear up without drainage. He described also three cases of acute nephritis treated with penicillin, all of which did well.

Baffling the Imagination

Mr. **Zachary Cope** said that in the case of staphylococcal septicaemia penicillin was "simply wonderful." It baffled the imagination to think what would follow the full development of this drug. Surgery was being revolutionized before their eyes, and the young men entering surgery now would have a very different outlook from their predecessors, concerning the reaction of the tissues and the like. He desired to ask Sir Alexander Fleming how often skin irritation of any kind occurred after using penicillin, and also his view concerning the reaction of penicillin in endocarditis. He himself had for years felt that there was a great deal which still remained to be understood about the reaction of the cellular tissues. He also asked what delay in the onset of syphilis had been noticed in certain cases after the clearing up of a gonococcal infection.

Mr. V. E. **Negus** referred to the use of penicillin in oto-laryngology. One of the great bugbears had been a fulminating sinusitis affecting a patient suddenly after swimming. Recently he saw a naval officer who, after a swim, developed a condition of severe staphylococcal septicaemia. He was treated with penicillin, and five days later he saw him at his military hospital taking part in a dance, whereas, without this treatment, his chances of being in his coffin by that time were considerable. Another patient developed a mediastinal abscess, with a temperature of 105°, and would have died, but was cured very quickly with penicillin.

Dr. C. E. **Lakin** asked whether it was possible to mix oil with penicillin so as to diminish the rate of absorption. Dr. G. W. **Goodhart** asked whether there was any evidence that the absence of leucocytosis in the blood had any bearing on the question of penicillin treatment. He mentioned two cases of staphylococcal septicaemia in which there was an extremely low leucocyte count. Dr. L. **Carlyle Lyon** asked whether any patients were known to be allergic to penicillin, also whether penicillin was useful in the tertiary stage of syphilis.

An "Umbrella" for Operation

Mr. E. W. **Riches** said that the organisms infecting the urinary tract—*B. coli*, for example—were not sensitive to penicillin. In his unit for spinal injuries he had seen a number of patients who had penicillin from the beginning, and it had not, of course, prevented urinary infection altogether. There was not a drug at present known which would entirely prevent infection. But penicillin had been extremely useful in helping to clear up cases in which the infection was mainly staphylococcal, and it had been used as an "umbrella" under which to operate in cases of stone formation and had helped to tide such cases over a difficult period.

Mr. R. C. **BROCK** said that in thoracic surgery they were looking forward to great benefits from penicillin, in particular in the after-care of pneumonectomies.

The **PRESIDENT** wished to take the opportunity of testifying to the remarkable effects of penicillin in many germ infections. He had seen, at a neurosurgical unit, a number of these cases, the result of gunshot injuries of the brain, and the value of penicillin there had been demonstrated. The surgeons sewed up the wound completely within a short time and no sinus infection developed later. He mentioned one recent case of a man agd 48 admitted to hospital with clear signs of meningitis. Lumbar puncture gave a turbid fluid. He was put on sulphathiazole. The culture showed a pure pneumococcus. Pneumococcal meningitis, particularly if no primary cause was discoverable, was accompanied by a high mortality even after the sulphonamide drugs were available. In this case the sulphonamide was continued, but the patient had two intrathecal injections of penicillin on two successive days, and got perfectly well and left the hospital within a week; he could hardly be persuaded to stay as long as that. Dr. Feiling mentioned two cases in which penicillin had failed. One was a staphylococcal septicaemia in a woman of nearly 70 who died in spite of continued intramuscular drip, and in whom post mortem no bacterial endocarditis was found. He had also tried penicillin, quite experimentally, in a very severe case of glandular fever, with continued high temperature and a most violently inflamed throat, both tonsils being very much enlarged, with a superficial necrosis on one tonsil. The penicillin gave no benefit, though the patient did recover spontaneously within about a week.

Sir **ALEXANDER FLEMING**, in reply, said that it was interesting to hear about the use of penicillin in glandular fever. If the micro-organism of glandular fever were known it would come within the insensitive category. That was the sort of case in which he would not expect a good result. Concerning skin irritation, this did occur sometimes, though not often, and was never serious. He had seen an American report concerning urticaria, but this seemed to occur with the use of pure penicillin, so that it was not to be attributed to one of the impurities. The Americans had made certain claims concerning the value of penicillin in endocarditis, but he himself had not much faith in the short-term treatment of that condition. In endocarditis penicillin had to diffuse into the "vegetation," and a certain concentration in the blood was necessary for a considerable period. Before long they might be expected to know more about the treatment of endocarditis by doses of 5 million units which was projected in America.

A question had been asked about the use of penicillin in the form of snuff. This was much more pleasant in the form of dried plasma with penicillin, and he was told that in some more or less acute nasal conditions it was a treatment worth trying. Endeavours had been made to delay the absorption of penicillin by means of oil, and one mixture was of an oil containing 5% of beeswax. This did seem to delay the absorption, but there were troubles in its preparation and injection.

He could only with difficulty answer the question about delay in the onset of syphilis. Air Cdre. McElligott had told him recently that he had had several cases where syphilis was delayed, after treatment for gonorrhoea, for from 60 to 80 days. As for the treatment of tertiary syphilis, he must refer the questioner to the American journals, for nobody in this country had experience of it. In the U.S.A. they had been using penicillin for general paralysis of the insane, and he had seen one report which stated that it was as good as malaria treatment.

Mr. Dickson Wright had suggested that surgery was going to disappear. That, of course, was an exaggeration. On the other hand, the use of penicillin would take away one at least of the surgeon's disabilities, for he need no longer wear a mask while operating.

Approximately 2,400 newspapers and periodicals were examined last year by the Law Department of the Pharmaceutical Society of Great Britain and its inspectors for advertisements, now forbidden, of "cures" for certain diseases. In many instances the Society had the advertisements amended without taking proceedings. A number of infringements were, with the consent of the Attorney-General, brought before the courts.

Correspondence

Nursing in Tuberculosis

SIR,—Much of the "tuberculophobia" which still exists a which is exhibited by some of your correspondents is sure based upon shibboleths which die a hard death. There is s little distinction drawn between infection by the tuber bacillus, which is universal, and tuberculous disease, which relatively uncommon. And there is very little appreciatio even among those who should know better, of the essenti difference between the innocuous manifestations of prima infection and progressive phthisis. The sanatorium nurse that much-photographed, much-investigated scapegoat for pr judice—is certainly infected during the course of her duti but no one, in spite of every effort, has been able to conv her of undue tuberculous morbidity. To be sure, the san torium nurse does not claim an *ex-officio* immunity to di ease, and a certain number of young women prove to unfavourable reactors. In this case there is always so bystander who will cry havoc.

The figures of Hansen of Oslo have been mentioned Dr. W. E. Snell (Feb. 10, p. 198), but Ustvedt, summarizi the work of all the Scandinavian workers in this field (wi particular reference to intensive investigations in connexi with infection and disease in hospital nurses), states:

> "Infective dose and virulence are factors which we can disrega . . . The type of bacillus may possibly play some part in countr where bovine tuberculosis is prevalent. . . . The role of superinf tion has not been fully elucidated, but it cannot be regarded all-important. . . . It therefore appears that on the whole t widely varying course of the tuberculous infection in differe individuals can only to a very slight degree be regarded as depe dent upon variations in the infection itself. We must turn to t infected organism to find the explanation."

It should be remembered that no other comparable gro of young women is submitted to such physical, mental, a psychological strain as is the hospital nurse, and that h conditions of work often leave a good deal to be desired.

Ustvedt, Jacobs, and other writers have also pointed c fallacies in the popular conception of the significance "massive infection" as a factor in the aetiology of tuberculo disease. Of far greater value is the growing appreciation the significance of environmental factors in aetiology, and pa ticularly of genetic factors, as demonstrated in the rece remarkable work in the United States on the incidence of tub culosis in twins.

Those who continue to speak of sanatorium nursing as hazardous undertaking should await the publication of the cl analysis of the health of sanatorium nurses which is promis by Drs. Edwards and Clark Penman (Jan. 20, p. 957), and other reports which are in process of preparation.—I am, et

Harefield County Hospital, Middlesex. L. E. HOUGHTON.

Solubility of Sulphadiazine

SIR,—In the leading article on sulphamerazine (Feb. 3, p. 1 it is stated that the solubility of sulphadiazine is 139 mg. 100 c.cm. at *p*H 7.6. From the preceding sentence this p sumably refers to solubility in urine. The figure quoted diff from the figure given in M.R.C. War Memorandum No. 10 "The Medical Use of Sulphonamides," in which it is stat that the solubility in urine at 37° is 52 mg. per 100 c.cm. I important to know which figure is right.

If the patient is taking 4 g. sulphadiazine a day, then, assumi 75% of this is excreted in the urine unchanged, there will be 3 in the urine. If the urine has a *p*H of 7.5—that is to s alkaline—the volume required to dissolve it will be 6 litr or 10 pints, if the solubility is 52 mg. per 100 c.cm. Since f patients excrete so much urine as this, many must suffer fr deposition of crystals in the urinary tract. If, however, solubility is 139 mg. per 100 c.cm. the same amount of sulp diazine will be excreted in 2.2 litres, or 4 pints. This is a v different story.—I am, etc.,

Department of Pharmacology, Oxford. J. H. BURN.

⁂ The figures given for the solubility of sulphadiazine ha varied somewhat in different papers. Thus in the origi scription by W. H. Feinstone, R. D. Williams, R. T. Wolff, E. untington, and M. L. Crossley (*Johns Hopk. Hosp. Bull.*, 1940, , 427) the solubility is given as 12 mg. per 100 c.cm. in water 37° C., 32 mg. in urine at *p*H 6.6, and 107–247 mg. in blood. R. Gilligan and N. Plummer (*Proc. Soc. exp. Biol.*, N.Y., 1943, ; 142) give a curve from which it can be deduced that the ubility is 100 mg. per 100 c.cm. at *p*H 7.2, about 223 mg. at H 7.5, and about 270 mg. at *p*H 7.6. In the paper by L. H. hmidt, H. B. Hughes, E. A. Badger, and I. G. Schmidt (*J. armacol.*, 1944, **81**, 17), which supplied the figures to which of. Burn refers, the solubility is given as 41.6 mg. per 100 m. at *p*H 6.8, 78.5 mg. at *p*H 7.2, and 130 mg. at *p*H 7.6. wever, all these authors are agreed that the solubility is comratively low in acid solution and that it is greatly increased the solution becomes slightly alkaline. It is understood that figures given in the M.R.C. Memorandum were based on earlier publications and that they will be revised in the ond edition (now being prepared) according to the fuller ormation now available.—ED., *B.M.J.*

Painful Intramuscular Injections

SIR,—Dr. Geoffrey Dean (Dec. 2, 1944, p. 737) doubts if it is iversally recognized how painful intramuscular injections of nicillin can be. It is not in fact widely recognized because ramuscular injections of penicillin are not invariably painful. ce, however, patients do suffer acute pain, which can be ided by simpler means than Dr. Dean suggests, it might well to examine the contributory factors in detail. These tors are the same as for any intramuscular injection—namely, The skill of the operator. (2) Efficiency of instruments. Nature of skin antiseptic. (4) Nature of substance injected. Position and attitude of patient. (6) Patient's threshold to in.

. Patients requiring penicillin now and for some time to me must be hospitalized, and therefore the operator for these -hourly injections is a senior nurse. It is inevitable with day d night staffs and changes for off duty, etc., that a fortunate tient will have at least three operators in any 24 hours. The bility to pain varies with the training and skill of the nurses, d in particular the variation is most marked in the rate of ertion of the needle and the rate of injection of solution. The xperienced pierce the skin slowly (and painfully) and proceed inject rapidly, giving rise to a particularly unpleasant stinging n of wide radiation. Contrariwise the injection which is tually painless results from a bold insertion of the needle and low (2 c.cm. per minute) rate of injection of solution. This ed of the procedure is the most important single factor in the duction of pain.

. The period of penicillin injections during the past two rs has been one in which the quality of steel allocated to dle manufacturers has deteriorated, and thus the life of the ting edge of a needle is shorter and requires more care—e.g., routine replacement of the stylet between use so that the jecting end prevents contact with, and injury by, other tallic objects.

. Spirit has become almost the only skin antiseptic in eral use for injections, intramuscular and intravenous, and artificial pneumothorax. It is a common experience that e patients complain of pain when submitting to injection material other than penicillin where this antiseptic is used. s pain is due in most instances to the irritant action of spirit ried from the skin by the needle to the soft tissues, and can avoided by using ether or ether meth. and allowing a few onds for evaporation before inserting the needle.

. It is recalled that many parenteral therapeutic agents— , liver extract, arsenicals, etc.—have been painful when first oduced, due to unsuitable *p*H and/or contained impurities. use of local analgesic is an uncertain method of minimizing n in these cases and converts a simple procedure into one ch is complicated and time-consuming.

. Recent letters in your columns have debated the respective antages of the buttock and the lateral thigh area, though no rence has been made to position—upright or recumbent. en the injection is made into the buttock in the upright ition the usual practice is to have the patient unsupported. however, the subject is allowed to lean on the edge of the or couch the glutei are relaxed, and as a result perhaps more long courses of treatment involving this method might be completed! In the bed-patient the gluteal injection is usually given when the patient is lying in the half-lateral position, so that it is made in an awkward vertical direction. Apart from other important considerations, the external vastus site is far more convenient, and makes an injection in the horizontal direction easier and less liable to pain.

6. Apart from the recognized variation of individuals in their pain threshold there is the patient's variation at different stages of the illness. This, as well as other points mentioned above, is clearly exemplified in the following account:

> A patient suffering from a staphylococcal septicaemia had a total of over 4,000,000 units of penicillin during various periods aggregating some nine weeks in a five-months illness. In the first few desperate days he was hypersensitive to handling of any sort, and penicillin injections by all but one (expert) person provoked a "refusal of treatment" reaction. This short period ended by an improvement in general condition and by the substitution of ether for spirit as a skin antiseptic. Injections were continued, and maintained due to relapse, for a period of eight weeks, and the ruthless monotony of 3-hourly day-and-night injections became a small factor in the patient's comfort provided the skin was cleaned with ether, the needle sharp, and the injection made slowly.
>
> After a remission of two months injections were resumed for one week, when 2 c.cm. (20,000 units) of penicillin was injected 3-hourly. There was no comparison at this stage with the condition of the patient at the beginning of the illness, and during each of the last 50 or so injections he didn't "turn a hair." He did, however, turn his head if a blunt needle necessitated two attempts to pierce the skin or if the rate of injection was raised! No local analgesic was used throughout, and the majority of injections were made laterally into the upper two-thirds of the thighs.

In view of the increasing use of the intramuscular route more training should be given to nurses and junior medical officers in the details of this procedure, and care should be shown in the selection of nurses delegated to give the injections. It is not enough to order therapy for a patient suffering from a severe general infective condition which will probably require a protracted series of injections for recovery, and to be satisfied if nurses whose aseptic technique and training are not fully established are left, eager but nervous, to undertake injections which may result in the disaster of a broken needle. It is not necessary to acquire all skill on human beings; there is the post-mortem room for doctors and the tennis ball (when obtainable) for nurses; and in any case for both there are the opportunities presented by the occasional single injection or the short series prescribed for conditions of local infections.—I am, etc.,

WM. DODD.

Injectable Liver Extracts

SIR,—In your issue of Feb. 10 (p. 197) Dr. Harold Fullerton called attention to the danger attending the use of injectable liver extracts that possess little or no potency. This is clearly a matter of much importance. I am strongly in favour of immediate steps being taken to obviate any such danger.

I suggest that this might be achieved by making it a compulsory requirement that every issued batch of injectable liver extract shall have been shown to have produced a satisfactory response when the dose recommended has been administered to not fewer than three cases of pernicious anaemia that have not been previously treated or are in relapse. This, however, does not involve an accurate standardization such as is implied by stating the activity in units. The use of the term "unit," as applied to medicinal substances, is inappropriate except where an exact determination of potency can be made, in comparison with that of a standard stable substance which has been rendered available for this purpose. This is surely not the case with injectable liver extracts, since the only known method of testing them is the administration to a patient.

To all pernicious anaemia patients presenting themselves for curative treatment there is an obligation to administer sufficient injectable liver extract to ensure a good haemopoietic response. Without an almost unlimited number of suitable cases, one cannot determine the degree of curative activity with the accuracy required for expressing it in units. On the other hand, it is quite possible to determine that a given number of c.cm. administered to patients will produce a satisfactory increase in the red blood cells in 10 to 14 days. This being determined on every batch in at least three typical cases may be taken to provide a sufficient assurance that the extract in question possesses full activity. It does not, on the other hand, justify attributing to it a numerical value in terms of units.—I am, etc.,

London, N.1. FRANCIS H. CARR.

? Otitic Barotrauma

SIR,—The writer of your annotation on barotrauma (Feb. 10, p. 190) rightly asserts that "aero-otitis media" was a misnomer. "There is," he writes, "no inflammatory change . . . and therefore in the interests alike of accuracy and euphony the term otitic barotrauma has now taken its place and has been adopted by the R.A.F."

I do not want to argue about the euphony, but does the writer not realize that "otitic" signifies as much inflammation as "otitis," and that, therefore, the term "otitic" barotrauma is just as inaccurate as its predecessor? Will Air Cdre. Dickson and his fellow workers be prepared to write "otitic" ganglion when the otic ganglion is referred to? If we assume that similar events could occur in the stomach, we might, in the absence of inflammatory changes, speak of "gastric barotrauma." "Gastritic barotrauma" entails no less inflammation than "aero-gastritis."

The term otic (or aural) barotrauma avoids the pitfall; but, while the condition is certainly not "otitic," it is also very doubtful whether it is "traumatic" in the usual medical sense of the word. I maintain that "tubo-tympanic pressure syndrome" (which I suggested in a discussion at the R.S.M.; *J. Laryng.*, 1943, 58, 493), while of doubtful euphony, designates the condition more accurately.—I am, etc.,

London, S.W.13. A. B. ALEXANDER.

Selenium Poisoning

SIR,—In your issue of Feb. 10 (p. 196) you report a meeting of the Nutrition Panel of the Food Group of the Society of Chemical Industry on the effect of diet on industrial poisoning. To me is attributed a reference "to work on selenium poisoning in which, by means of labelled molecules, it has been shown that selenium took the place of sulphur in the methionine molecule, and hence caused what might almost be described as a conditioned protein deficiency." I fear that the reporter in a laudable attempt to condense my discursive remarks has attributed to me something that I did not say. I have already had one inquiry for the reference to the work to which I am reported to have alluded. To the best of my recollection, this was what happened. In the course of the discussion a speaker mentioned the selenium poisoning of cattle and the theory (not his own) that this might be due to its substitution for sulphur in the sulphur-containing amino-acids of proteins. In my remarks I called attention to some recently published work by du Vigneaud and his colleagues, in which it has been shown by the use of labelled elements that the sulphur of methionine is required for *in vivo* conversion to cystine, whereas the carbon chain of methionine does not appear in the cystine molecule. Putting the theory and the fact together, I suggested the possibility that selenium might thus interfere with the *in vitro* synthesis of cystine. But there is no experimental evidence for this purely speculative view, nor, so far as I am aware, has any biological work yet been carried out with labelled selenium.—I am, etc.,

Greenford, Middlesex. A. L. BACHARACH.

Choline for Fatty Livers

SIR,—I have read with interest the article by Drs. Alexander and Eiser (Sept. 30, 1944, p. 425) and the letter from Dr. Lewes (Oct. 28, p. 575) on infantile diarrhoea and vomiting. In 1939 Martin Hynes and I were working on this problem when a milk salesman put me on to some work by Wilkinson, Best, *et al.*, done, I think, at Liverpool, the gist of which was, that if rats were fed on a "fatty-liver-producing" diet they could be protected against getting fatty livers by the addition of protein to their diet. Impurities in the protein were found to be the active agents, choline being the one ultimately named. A fatty liver being so constant a post-mortem finding in this disease, we thought to protect our patients from it by giving them choline. Choline was difficult to get, but a preparation was found. The war intervened before a series could be treated in this way. I am certain the prevention of the fatty liver, if this is possib will improve the prognosis, and suggest that choline may be means of doing this. With this in view it would be interesti to know the choline content of the hydrolysates used at Sout end.—I am, etc.,

R. E. BONHAM-CARTER.
Germany. Capt., R.A.M.C.

Breathing and Coronary Circulation

SIR,—My letter published on Jan. 6 (p. 27) might have bee written especially for members of the medical profession, f the death rate among doctors is 40% higher than among bar officials in the same social group. "Surgeon" (Jan. 20, p. 9 is to be congratulated on being treated so skilfully by Dr. A. Todd, who advocates breathing with the mouth open and wh standing. The patient when breathing should be seated—all t muscles of the body should be relaxed, even the facial muscle the shoulders should be held gently back and down, by t muscles acting just below the scapulae, 3 in. below t axillae. Mr. F. Matthias Alexander (author of *Constructi Conscious Control of the Individual*) would state that t relaxation of the chest muscles is important using only tho previously mentioned, otherwise the range of movement the thorax would be impeded. The first exercise is breathe fully in and out deeply through the nostrils, t shoulders being first drawn back and down; the second is inhale fully and then hold the breath for 15 to 60 seconds longer; and the third is to exhale completely and then ho the breath for 15 to 60 seconds or longer. By keeping t shoulders down and back when standing, sitting, writing, a stooping, the necessary movement of the chest is carried unconsciously, and the same happens at night, when lying, sa on the right side if the left elbow is placed just behind the lo axis of the body. When standing the weight of the body shou be on the balls of the toes. This way of breathing, besides he ing the heart, is a wonderful restorative to all the remaini organs of the body.—I am, etc.,

Ealing, W.5. R. HALSTEAD DIXON.

Impetigo

SIR,—Surg. Lieut. J. Munro Gold's memorandum on impeti treated by sodium penicillin (Feb. 3, p. 152) was extreme interesting, but I think calls for some comment.

1. He found acriflavine 1/2 gr., tannic acid 20 g., and wa to 1 oz. unsuccessful. To my mind the failure was probab due to the fact that the lotion was too strong—half the abo strength might have shown good results.

2. Failure occurred when ung. hydrarg. ammon. dil. w used; here again, unless the patient was sensitive to mercu the preparation was too strong. The late Sir Norman Walk advised that 5 gr. of hydrarg. ammon. to the oz. should be use and years of experience have shown me the correctness of t advice. I believe that the reason why hydrarg. ammon. h fallen into disfavour is because this advice has been neglect

3. The ointment base for the penicillin was described as t soft. It consisted of equal parts of cod-liver oil, lanolin, a water. Might I suggest to Surg. Lieut. Gold that the n time he uses penicillin he should try 5% lanolin, 20% wat and 75% liquid paraffin if a soft cream is required, or 75 paraffin. molle if a firmer cream is wanted.

I do hope he will understand the spirit in which I make th remarks. I enjoyed his well-written article and I feel that has done dermatology a great service, for, like the po impetigo is always with us, and its treatment has many ang and pitfalls.—I am, etc.,

Paignton ARTHUR J. AMBROSE.

Artificial Insemination

SIR,—Artificial insemination of a wife by her husban semen is a very different matter from a similar procedure which the semen comes from another selected man or from pool.

In every civilized community parenthood carries respon bilities for the care and upbringing of the child. It is diffic to understand how any reasonable man can in cold blo consent to take part in the procreation of children in wh upbringing he deliberately refuses to take part. Such cond conflicts with all civilized standards of rectitude, and would seem unwise even on grounds of expediency.—I am, etc.,

London, W.1. V. ZACHARY COPE.

SIR,—Not everyone would willingly become involved in this discussion on artificial insemination, but loyalty to the traditions and good name of medicine may sometimes transcend personal inclinations, and therefore I do not propose to let Mr. Kenneth Walker (Feb. 10, p. 199) disappear behind the smoke screen of a quotation from Voltaire. For all the relevance this has to his thesis, he might as well have ended his letter by inditing "Rule, Britannia." No one objects to his stating his ethical position; the objection is that he appears to have none. His situation is that artificial insemination by donated semen is practicable and therefore requires no other justification. What the cattle breeder does, we may do.

Let us look this business fully in the face so that all its implications may be clear. We are told that the qualifications of the human stallion, and what is asked of him, are that he shall be a married man of "intellectual attainments," between 30 and 45 years of age, and the father of two legitimate children. He should be of high fecundity, acceptable character and viability, and his "other qualifications" must meet with the august approval of the specialist in the new science of siphoseminology. He must be subjected to periodical tests of his seminal products, and should he be willing and able to deliver these to the laboratory twice weekly—presumably in a plain van—he might theoretically become the father of 400 children a week. However, his total of offspring is to be arbitrarily limited to 100, after which he retires upon his well-earned laurels. In his unsearchable wisdom the inseminator will decide which of his private stud of human stallions best meets the needs of the particular female candidate for insemination. The donor's wife finds no mention in this prospectus. Presumably the donor must keep from her the secret of his perverted philoprogenitive cravings, or he will need a wife as degraded as himself, one who, the mother of two of his children, does not object to his acting as sire to an indefinite number of human females.

One can but marvel at the grandiose frame of mind of the inseminator, who conceives himself fit to assume these superhuman prerogatives, and to people the land with a new race that shall improve upon the handiwork of Providence. In time, doubtless, we shall be presented—in due scientific form—with an analysis of the careers and achievements of these siphogens.

But this is not all. If so much is unobjectionable, the business can surely with equal freedom from reproach be carried still further. There must be unmarried women whose lives might be rounded off by maternity. Why not render this "service" available to them? Then there are thousands of married men over-seas unable to raise families. Might not these wish to give some sort of power of attorney to the inseminator, to permit his donors and his syringe to act as proxy for them? If we begin where are we to stop? Why stop, indeed, short of exploring the full possibilities of the new technique? A syringe has no ethics, and can impart no ethical sanction to a transaction of this order. Why bother about it? After all, ethics are merely a matter of "feeling," which is Mr. Kenneth Walker's naive way of saying that a little of what you fancy makes you good.

When techniques come into the irresponsible hands of the ethically rootless they are a constant threat to both intellectual and ethical values, as we may see when we gaze round us upon a world in which man is torn and tormented by the fruits of techniques he has neither the wisdom nor the sense of values to control. Medicine now is being invaded by this evil, and every thoughtful doctor who holds dear the traditions of medicine as a humane and learned profession must feel called upon to protest in unequivocal language.—I am, etc.,

London, W.1. F. M. R. WALSHE.

SIR,—While reading the other day the chapter on sterility in *Diseases of Women*, by Ten Teachers (1930 ad.), I came across the following passage relative to artificial insemination. "This method is successful sometimes with domestic animals, but is naturally somewhat repugnant to *normal* human beings, though some women resort to it in desperation." (The italics are mine.)

In a letter (not published) which I sent to you several months ago on this subject there occurred the following questions: "What sort of a woman is it who demands artificial insemination? If the maternal urge in a childless woman cannot be satisfied by the adoption of a suitable child, is she not better without one altogether?" The question is whether she is concerned about the thwarting of her own feelings of motherly love or whether it is her own sense of frustration and inferiority as compared with other women who have children which troubles her most. One suspects such women of having a neuropathic tendency, and it would be of interest to see the life history of the offspring of this method of procreation for evidence of psychoneurosis which they might inherit from the maternal side.

We have yet to have the views of the leaders of the profession in the realm of obstetrics and gynaecology as to this seemingly thorny question, which bristles with moral, if not medical, difficulties. One imagines that the stomachs of the average medical man and woman, in spite of nearly six years of war and Nazi horrors, still retain sufficient sensitivity to experience some feelings of antiperistalsis when discussing this subject.—I am, etc.,

Hove. G. L. DAVIES.

SIR,—Recent letters on the subject of artificial insemination reveal a peculiar emotional attitude in many of your correspondents. They seem to regard the operation with the same sort of horror which antivivisectionists and antivaccinationists have towards their pet aversions.

It is difficult to obtain any idea of the extent to which artificial insemination may be used, but the number of operations will undoubtedly be small, and may possibly be insignificant when compared with the number of illegitimate pregnancies, the number of illegal operations, or the number of pregnancies averted by contraception. To me the matter is one purely for the consciences of the applicants, and if a couple wish to resort to this method to obtain a child they should be allowed to do so, as the alternative would seem to be for the wife to commit adultery, which is just as illegal and unethical.—I am, etc.,

Hebburn, Co Durham. J. A. FORREST.

Health of Children in Day Nurseries, 1944

SIR,—Referring to recent correspondence in connexion with the health of children in wartime day nurseries, the accompanying figures may be of interest. As some of the data on which diagnoses were based were somewhat vague the figures can be accepted only provisionally and regarded merely as a rough indication of the extent of illness in the Halifax wartime nurseries. So far as I can ascertain (and allowing for the difficulties and inadequacy of morbidity statistics) they compare favourably with morbidity rates for non-nursery children in this area.—I am, etc.,

Psychology's Opportunity

SIR,—It seems a pity that the *Journal* should, through an editorial note to a letter from one of its correspondents (Feb. 3, p. 164), ascribe (even though only partially and by implication) the great successes of the Red Army to an "aggressive instinct" traditional to our Allies. The manner in which they have endured hardships appalling to contemplate and yet have preserved their ability to stage colossal victories has been ascribed to an infinite capacity for suffering, a docile patience, an animal-like willingness to accept discipline imposed from above, a reckless disregard for human sacrifice, and other qualities supposedly traditional to the Russian peasant or to the "Slav" temperament. That any degree of credence should be given to such an unscientific view in a reputedly scientific journal is regrettable. It would appear that Red Army men are themselves getting rather tired of this explanation for their deeds of prowess. An article in a recent issue of *Red Star* (the newspaper of the Red Army) says:

> "It is time to see us for what we are—to study us, not from old fables and legends, or even from Dostoyevsky, but from a current textbook—our present-day deeds and our living people. . . . Foreigners are astonished at our victories. The world must have been asleep. It failed to see that we were learning to write, to build, and to fight. We are winning to-day not because our Cossacks are dashing, or because of the infinite docility of the old Russian soldier. The Red Army man knows why he is fighting and for what. And if certain foreign wiseacres know that the Red Army is winning thanks to the traditional qualities of the Russian soldier, we are entitled to retort: 'You praise Platon Karatayev only because you don't like the October Revolution.'"

The Russians evidently attribute their victories to their socialist way of life. They, of all people, should know.—I am, etc.,

Cymla, Neath. T. Francis Jarman.

Sir,—With all deference may I point out that your note under Dr. Tandy Cannon's admirable letter (Feb. 3, p. 163) in no wise weakens, much less nullifies, the truth of the latter's thesis, your note being in the nature of an *argumentum ad hominem*. The "aggressive instinct" of the Russians in its present manifestation is comparable to the surgeon's knife when used (granted without an anaesthetic) to extirpate a cancer threatening the welfare, and indeed the life, of every nation, including that of Germany itself.—I am, etc.,

Royal Societies Club, London. George S. Brock.

Demobilization and the E.M.S.

Sir,—I feel that the letter of "E.M.S." (*Journal*, Jan. 20, p. 97) calls for further comment. Certainly the majority of Service M.O.s do not spend more than a small proportion of their time sitting beside a slit trench; nevertheless, they have sustained a considerably higher mortality and morbidity than E.M.S. officers. This, however, is beside the point, and in actual fact the tedium of uneventful patrols at sea is often harder to bear than the dangers of enemy action. The essential point is that while "E.M.S." has continued to do professional work and to increase his post-war market value by the acquisition of a diploma in anaesthetics, we in the Services have lost through disuse much of our skill and gained little beyond a well-found cynicism.

"E.M.S." speaks of the compensations of Service medicine with little sense of reality; the rank of lieutenant after five years loses its glamour, while the promised gratuity will not pay for the re-education we shall require.

Mutual recriminations, of course, are entirely profitless, but one solution does present itself. The release of E.M.S. officers for the Services would allow them to have their share of travel and prestige; while Service M.O.s (who might, after all, have escaped the London "blitz" because they were in Crete or Tobruk) would gladly take their place in the E.M.S. Incidentally it might interest "E.M.S." to know that "blitzed" homes are not confined to civilian doctors. I also have had my wife and child bombed out.—I am, etc., "R.N.V.R."

Service Medicine

Sir,—As a chemist whose children are both budding "medicals," I have followed with interest the recent correspondence in the *Journal* about Service medicine. So, apparently, has my son, now serving with a specialist R.A.M.C. unit over-seas, where he has come into contact with a large number of medical officers of all types. Because he has thus had a good opportunity of gauging the opinion of the younger medical officers, and has written to me quite frankly what he thinks on this subject, with no notion whatever of publication, you may think it useful to reproduce the relevant part of his letter which I give below, with only such slight elisions as are necessary to preserve anonymity.

> "There has been a lot of mud-slinging in the *B.M.J.* recently. Several (obviously junior) officers have written letters, hiding behind screens like 'Temporary Serving Officer.' They have all said that Service medicine was a very poor show because they didn't see enough sick men, and because promotion was too much on the 'old chap' basis and not on the 'clever boy' basis. More senior officers than I had realized to exist in the Medical Services have haughtily stood their ground in the face of this mutiny. What they say is roughly: (1) Patients are better treated in the Army than in civil life (I agree about this). (2) Doctors in the Army must administrate as well as ministrate. (I'm afraid this is too true.) (3) The cowardly chaps who write these letters anonymously are in a minority. Most M.O.s love the dear old Army. They seem sure about this. I am equally sure that most junior medical officers in the various Services feel they would prefer to have a job in a civilian hospital. The only way these scribes are in a minority is that they think it will do any good to write letters about it. Most M.O.s just manage to be cheerful and to do what little work is offered to them. Mostly they feel it is in bad taste to complain about their lot when men skilled at other jobs have an even more unprofitable time in the Army, as well as a more dangerous time. Mostly they lapse into a shock-absorbing state of relaxation about the whole business.
>
> In the Army there are two different kinds of medical officer: (1) There are middle-aged men hoiked out of their lucrative general practices to try and pay their life insurance premiums on a captain's pittance—as it seems to them. They rather resent the fact that they are pushed around by adolescent young puppies with the rank of major or colonel. And it's much rougher, I suspect, to be uprooted at the age of 40 than it is at the age of 30. So the middle-aged G.D.O.s (general duty officers) are the hardest-treated ones. (2) There are newly qualified chaps being paid what they regard as a princely salary for doing less work than they ever did before. Like everyone nowadays they want to be specialists, but they hadn't been qualified long enough in civil life to realize that they would have to be G.P.s. As time passes they are coming to see it anyway, and they blame it on the Army. These are the ones most of whom *don't* write letters to the *B.M.J.*
>
> But the brigadiers writing letters in the *B.M.J.* are wrong if they imagine that most medical officers really like the Army. The more cheerful ones try to cheer up the gloomier ones by pointing out its brighter side. And, of course, anyone speaking to a brigadier tries to give the impression that he's a happy and contented sort of bloke, but when Major X and I, in our travels, met a medical officer who did really prefer the Army to civil medicine we drew back from him as we would from someone who announced, 'I'm Napoleon.' If there had been a brigadier in the room his behaviour might have been understood, but there wasn't. Anyway, one of the good things about the Army is that most brigadiers are human, and don't particularly like being Army doctors themselves, though they quite enjoy being brigadiers."

—I am, etc., University Teacher.

WAR INJURIES

EXHIBITION OF SPECIMENS

After the destruction by enemy action in 1941 of the Army Medical War Collection housed in the Museum of the Royal College of Surgeons, London, the Medical Research Council accepted a request from the War Office and the Royal College of Surgeons of England that they should assist with arrangements for forming a comprehensive national collection of pathological specimens, photographs, and drawings of war injuries, which would serve both for teaching purposes and as a permanent record of the types of injury sustained in the present conflict. A special subcommittee of the Council's War Wounds Committee was appointed to direct the scheme; this subcommittee includes nominees of the three Services, the Ministry of Health, the Department of Health for Scotland, the Royal College of Physicians of London, the Royal College of Surgeons of England, and the Ministry of Pensions. The arrangements for the collection were entrusted to Dr. Joan M. Ross, who is acting as temporary curator.

A large number of specimens have now been accumulated, and by kind permission of the Royal Society of Medicine an exhibition of a selection of these is to be held in the Society's Council Room from March 5 till March 9, both days inclusive, from 9 a.m. until 6 p.m. The exhibition will be open to all members of the medical profession, but not to the general public. The exhibition will consist mainly of specimens, photographs, and drawings of wounds sustained in the land fighting in Italy and North-West Europe, which have been collected with the co-operation of the Army Medical Department. It will include museum specimens, collected by Dr. Ross; coloured photographs by Mr. P. G. Hennell (by courtesy of the Metal Box Co., Ltd.); drawings by Mrs. M. L. Wright and Mrs. Ehrenborg. It is hoped that all medical men or women having specimens of relevant interest to offer to the national collection will communicate with Dr. Ross, Science Block, Mill Hill School, London, N.W.7 (Mill Hill 3640). It is intended that the specimens collected shall be distributed to appropriate museums and teaching institutions after the war.

Obituary

E. A. PETERS, M.D., F.R.C.S.

Mr. Edwin Arthur Peters, consulting surgeon to the nose, throat, and ear department of University College Hospital and to the Bolingbroke and Paddington Green Children's Hospitals, died in London on Jan. 29.

He took a first-class in the Natural Sciences Tripos at Cambridge and the M.D. degree in 1900. In 1903 he took the F.R.C.S.Eng. He soon decided to devote himself to ear, nose, and throat practice, and was appointed to the staff of the Royal Ear Hospital, which was subsequently amalgamated with University College Hospital, and later to the Bolingbroke and Paddington Green Children's Hospitals. He was an active member of the Laryngological and Otological Sections of the Royal Society of Medicine and occupied the presidential chair in the latter. During the last war he became a captain, R.A.M.C., and was in charge of the nose, throat, and ear department of the Royal Victoria Hospital, Netley.

Mr. Peters's main literary contribution was his association with Richard Lake in the later editions of the well-known manual *Diseases of the Ear*, but he also contributed a number of articles on the special subjects in various journals. During his younger days he carried out investigations on the distribution of the peripheral nerves and the bacteriology of diphtheria. With the late Dennis Embleton he collaborated in an inquiry into the relation of sphenoidal sinus infections with cerebrospinal meningitis. He was intensely interested in the clinical side of his subjects and was a most regular attendant in his hospital departments. He always welcomed the visit of a colleague, and willingly gave of his knowledge in solving difficult problems.

In private life he had many hobbies—yachting, shooting, and carpentry among others—and he was devoted to country life. He was married twice, first to Alice Serjeant, by whom he had two daughters, one of whom is the well-known industrial dermatologist and the other an artist of distinction. Later he married Margaret Mains, by whom he leaves two children, a boy and a girl.

The medical profession has suffered a great loss by the untimely death at the age of 39 of Hugh Carmalt. He was in practice in Birmingham until August, 1939, when he joined his Territorial battalion. He served over-seas until the Dunkirk evacuation, and was awarded the *M.C.* for the part he played in this. It was in the intensive training period that followed Dunkirk that his fatal disability was caused—a chafing gaiter on the march, a phlebitis, a coronary thrombosis, and permanent invalidism. His outstanding quality of courage which had been recognized by his military award was now evident to all who came in contact with him. The struggle against his affliction won the admiration of a large circle of medical and non-medical friends. He tried to return to general practice, was seriously ill again, recovered a measure of his former health, and determined to break new ground. He entered upon a course of studies at Moorfields, and in July of last year successfully completed the first part of the D.O.M.S. examination. Within a fortnight of the date on which he had entered to sit for the final part of the D.O.M.S. his long illness had a sudden fatal termination. Hugh Carmalt had a great gift of patience which endeared him to many hundreds of patients before the war and stood him in good stead in the last uneasy months of his life. He leaves a widow and two young children.—L. H. G. M.

Dr. Robert Fenner died in retirement on Dec. 10 at Liphook aged 85, having continued in active practice up to the age of 80. He qualified at the age of 21 from King's College Hospital, where as a student he had been dresser to Lord Lister, and spent a couple of years after qualification as medical officer to the copper mines at Betts Cove and Tilt Cove, Newfoundland. His work there gained him the Fellowship of the Royal Geographical Society. He practised for many years at Cromer, where he attended numerous well-known people, including the late Emperor of Austria and King Edward VII. He moved to London in 1897 and worked for many years more in partnership with the late Sir M. Abbot-Anderson, and in 1898 he accompanied Kaiser Wilhelm II and his Empress on their tour to Palestine. He was well known at the Royal Thames Yacht Club and at one time owned the yacht *Chough*. During the last war he was chief constable of the Marylebone Police Volunteers and head of the Thames Police Patrol. That war brought him cruel losses, for his two sons were killed in 1917 and 1918, one in the Scots Guards and the other in the Navy, and his daughter also died, but he found some consolation afterwards in a particularly happy second marriage late in life. Fenner was a man of handsome appearance, combined with a most courteous manner and kindly disposition, and it is not surprising that he retained the confidence of so many distinguished patients. The outbreak of the present war compelled him to leave London at the end of 1939, and he had outlived many of his friends, but those who remain will remember his striking figure and, above all, his kindness and loyalty. They will be glad to know that he retained his vigorous personality to the end and died quickly from a cardiac attack, with little suffering

Dr. George Shepherd Wilson, for 12 years medical superintendent of the Durham County Mental Hospital, Winterton, Sedgefield, Stockton-on-Tees, died on Jan. 31 at the age of 47. He was a native of Greenock and was educated at Glasgow University, where he graduated M.B., Ch.B. in 1921. He saw service in the war of 1914–18 and was invalided out of the Army as a result of becoming a gas casualty. After graduation he acted as house-surgeon in the Glasgow Western Infirmary, and from there went to the Lancashire County Mental Hospital at Prestwich. He obtained his D.P.M. in 1929 and relinquished the post of first assistant at Prestwich to become medical superintendent of the hospital at Winterton. His twelve years in the County of Durham were indeed fruitful, and it was due to his energy and vision that the present modern units—reception and administrative—took shape and expression. He promoted and directed the establishment of psychological clinics at Darlington and Durham City, and he was ever eager to apply the most modern methods to the treatment of the mentally afflicted. The outbreak of war added fresh burdens to an already crowded life, and it fell to his lot to found and to guide the Emergency Medical Services Hospital, which many will remember with pride and gratitude. Despite all demands upon his strength and attention he never failed to give of his best.

Robert Blair Kinloch, M.B.Lond., who had been in general practice in St. Albans since 1904, died on Feb. 5 at St. Bartholomew's Hospital at St. Albans after a very brief illness, at the age of 69. He was born in Cardiff in 1875, and crowned his career at St. Thomas's Hospital by winning the Mead Medal. A correspondent writes: Dr. Kinloch was unsurpassed in St. Albans as an obstetrician, and few were his equals as an anaesthetist. He was truly a family doctor, for he devoted himself to his patients, and they in turn were devoted to him. His work was his life, and his patients loved him for his unfailing kindness and gentleness, so that he became not only their doctor but their guide and counsellor and trusted confidant, for his advice was sought on all manner of subjects. He would never commit himself to an answer until he had turned the matter over in his mind for some time, thus ensuring that his answer, when given, carried the full weight of his mature thought. In the first world war he served in France, and was for a time at Ostrahove Camp at Boulogne. His second son, Robert Alastair Boys Kinloch, M.B., captain, R.A.M.C., was killed in Burma in May, 1944, while acting as R.M.O. to the 1st Btn. King's Regiment. This tragic news, coupled with strain from overwork (for he never spared himself) and a serious collapse early in 1941, was undoubtedly a contributory cause of Dr. Kinloch's death.

The Services

The appointment of Surgeon Vice-Admiral Sir Sheldon Dudley, K.C.B., M.D., F.R.C.P., F.R.S., as Medical Director-General of the Navy has been extended for a further six months from July 2, 1945

Col. N. C. Speight, N.Z.M.F., has been appointed C.B.E. (Military Division), and Brig. J. M. Twhigg, D.S.O., N.Z.M.F., has been mentioned in dispatches, in recognition of gallant and distinguished services in the South Pacific during the period Feb. 1 to July 31, 1944.

The King of Egypt has conferred the Insignia of the Third Class of the Order of the Nile on Lieut.-Col. A. G. Harsant, O.B.E., R.A.M.C., on the occasion of his retirement as professor of clinical surgery in the Faculty of Medicine at Fouad University.

Surg. Lieut. E. J. Gilmore, R.I.N.V.R., has been commended for good services in fire-fighting after an explosion at Bombay Docks

CASUALTIES IN THE MEDICAL SERVICES

Officially reported died of wounds.—Capt. Reidar Scott Holtan, R.A.M.C.

Medical Notes in Parliament

Increased Grants to Universities and Medical Schools

On Feb. 13 Mr. Salt and Sir E. Graham-Little asked the Chancellor of the Exchequer whether he was now in a position to make a statement on the provision to be made to meet the post-war requirements of the universities. Sir John Anderson replied: I have carefully considered the report made to me by the University Grants Committee on the probable financial needs of the universities in Great Britain during the first decade after the war, and I have also had the advantage of hearing the views of a deputation of representatives of the universities and university colleges. It is clear that if the universities are to play the part they should in the reconstruction of our national life after the war they will have to incur expenditure on a very much higher scale than before the war. It is also clear that if the future financial needs of the universities are to be met, a large share of this new expenditure will have to be met by the Exchequer. As regards recurrent expenditure, it is not easy to forecast with any accuracy what will be the actual expenditure of the universities during the transitional period between war and peace. Both the University Grants Committee and the universities themselves have emphasized the importance of not sacrificing quality to quantity, and it follows that in the immediate future the supply of adequately qualified staff will be a limiting factor on development. The increased expenditure to be incurred by the universities will not, therefore, be spread equally over the 10-years period of the Committee's review. It will be heavier during the later than the earlier years of the decade, and the Government recognizes that the grants to universities during those later years will need to be further and substantially increased above the level now proposed for the next two years.

The University Grants Committee has recommended that the present annual vote for the universities of £2,149,000 should be increased for each of the next two financial years by the addition of £2,000,000 for general university purposes, £1,000,000 for developments in the medical schools arising out of the recommendations of the Interdepartmental Committee on Medical Schools, and £500,000 for grants for teaching hospitals as recommended by that committee. The Government has decided to accept the recommendations of the University Grants Committee for the two years in question. The question of the grant for future years will need to be reviewed at the end of the two years.

With regard to expenditure for capital purposes, the needs of the universities have in the past been met for the most part by private benefactions. I am advised by the University Grants Committee and the universities that this source of support cannot be expected to meet the needs of the universities for capital developments in the years following the war, and that if the building programmes of the universities are to be carried out a large share of the cost will have to be met from the Exchequer. The University Grants Committee has estimated that the universities will need to expend about £18,750,000, calculated at pre-war prices, on capital developments during the decade, and the Interdepartmental Committee on Medical Schools estimated that an additional sum of £10,000,000 (also at pre-war prices) will be required for developments in the medical schools. The Government accepts these estimates as indications of the probable scale of necessary capital developments, and recognizes that a very substantial proportion of the money will have to be provided from the Exchequer.

In view of the restrictions on buildings which are likely to operate during the years immediately after the war, it seems unlikely that the universities will have opportunities for any considerable capital expenditure during the next year or two. In the circumstances it seems to me that it will be sufficient to include in the Estimates for the coming year a token sum of £250,000 for distribution by the University Grants Committee, without prejudice to what may be necessary in later years. Accordingly, I am including in the 1945 Estimates £5,900,000 as a grant-in-aid of universities, colleges, medical schools, and teaching hospitals (Great Britain). It should not be assumed, however, that this amount will need to be distributed in grant within the financial year. This matter will be within the discretion of the University Grants Committee, which will review the position from time to time in the light of developments and may elect to retain part of the provision in the deposit account into which the grant-in-aid will, as usual, be paid. Any amount so retained will not in any case be liable to surrender to the Exchequer at the end of the year, but will remain available for distribution in the future.

Replying to questions, Sir John Anderson said that in the event of the £250,000, which was really not much more than a token sum, proving insufficient, the possibility of its being increased within the financial year would certainly not be ruled out. Dr. Summerskill asked what period of grace the Chancellor proposed to give those medical schools which now only admitted men to allow them to make arrangements for the admission of women before he withheld grants in those cases where they refused to do that. Sir John Anderson: I am glad to say that that particular question has not so far come within my jurisdiction.

Diphtheria in Lincolnshire

Asked on Feb. 8 by Mr. Viant how many cases of diphtheria had been notified in the three divisions of Lincolnshire since 1939, and how many deaths from that disease had been recorded in those areas, Mr. Willink provided the following table:

	Holland (A.C.)		Kesteven (A.C.)		Lindsey (A.C. and Associated C.B.s)	
	Notns.	Deaths	Notns.	Deaths	Notns.	Deaths
1940 ..	54	3	85	4	339	12
1941 ..	61	4	50	4	323	18
1942 ..	72	2	32	2	383	11
1943 ..	19	0	22	4	397	16
1944 (1st 3 quarters)	13 (a) 6 (b)		12 (a) 12 (b)		239 (a) 216 (b)	

Notes

1. All the notifications and deaths refer to civilians only.
2. The notifications for the years 1940–3 allow for such partial corrections of original notifications as were supplied to the Registrar-General.
3. For 1944 notifications are for the first three quarters of the year and no figures for deaths are yet available: (a) represents the numbers originally notified and (b) the numbers as finally corrected.

Protective Power of Vaccination

On Feb. 14 Sir James Grigg, replying to Mr. Leach, said it had never been claimed that vaccination conferred 100% immunity against smallpox in all cases and under all conditions. The maximum degree of immunity was estimated to develop about 14 days after vaccination; thereafter it gradually waned, but it remained effective, under normal conditions, for five years in the United Kingdom and for three years in Egypt, where the risk of infection was somewhat greater. During an epidemic, whenever it occurred, the virulence of the infecting agent was such that even the maximum degree of immunity conferred by immediate revaccination was not in every individual case sufficient to resist the disease. Nevertheless, experience had shown that the revaccination of all exposed to infection, coupled with the normal precautions of immediate isolation of infected persons and restriction of movement of possible "contacts," was successful in giving immunity to all but a small proportion and in quelling an epidemic.

Universities and Colleges

UNIVERSITY OF OXFORD

Somerville College announces that Miss Helen Darbishire will be succeeded as Principal of the College by Dr. Janet M. Vaughan, F.R.C.P. Dr. Vaughan is medical officer in charge of the North-West London Blood Supply Depot for the Medical Research Council. She was an undergraduate of Somerville College and took a first class in physiology in 1922 and her D.M. in 1930. She has been a Rockefeller Fellow, a Beit Memorial Fellow, and a Leverhulme Fellow, has held the post of assistant clinical pathologist at University College Hospital and the British Postgraduate Medical School. Her book, *The Anaemias*, is in its second edition. She was a member of the Interdepartmental Committee on Medical Schools (the Goodenough Committee), and is now a member of the Royal Commission on Equal Pay and of the body appointed by the Government to investigate public health in India.

UNIVERSITY OF CAMBRIDGE

At a Congregation held on March 2 the following medical and surgical degrees were conferred:

M.D.—R. I. N. Greaves.

M.B., B.Chir.—(All by proxy) C. D. Drew, H. H. E. Batten, D. W. R. Lyle, I. A. Magnus, T. J. S. Patterson, A. N. Pearson.

Medical News

A general meeting of the Medical Society for the Study of Venereal Diseases will be held at 11, Chandos Street, W., to-day (Saturday, Feb. 24) at 2.30 p.m., to consider the proposals of the committee of the society on "The General Principles of Administration and Staffing of the V.D. Clinics." The discussion will be opened by Dr. I. N. Orpwood Price.

The Royal Sanitary Institute has postponed the sessional meeting to have been held in Liverpool to-day (Feb. 24).

Dr. H. B. Morgan, M.P., medical adviser to the Trades Union Congress, will deliver an address on "Health and Industry" to a meeting of the Polish Medical Association in the United Kingdom on Tuesday, Feb. 27, at 5 p.m. in the Hastings Hall of B.M.A. House. All who are interested will be welcome.

The following films will be shown by the Scientific Film Association at the Royal Society of Medicine, 1, Wimpole Street, W., on Wednesday, Feb. 28, at 5.30 and again at 8 p.m.: "Mass Radiography," "Motion Pictures of the Larynx," "Liver Fluke," "Accident Service." Admission will be by ticket only, and application should be made immediately to the honorary secretary of the Medical Committee, Dr. S. J. Reynolds, 14, Hopton Road, London, S.W.16.

A meeting of the Council of the Medical Superintendents' Society will be held at Queen's (L.M.S.) Hotel, Birmingham, on Saturday, March 3, at 10 a.m., and will be continued on March 4 if necessary.

Sir Henry Dale, P.R.S., will deliver three lectures on "Nerve-endings and Chemical Transmitters" before the Royal Institution, 21, Albemarle Street, W., on Tuesdays, March 6, 13, and 20, at 5.15 p.m.

The annual general meeting of the Society of Public Analysts and Other Analytical Chemists will be held at the Chemical Society's Rooms, Burlington House, Piccadilly, W., on Friday, March 9, at 3.15 p.m., and will be followed by the presidential address by Mr. S. Ernest Melling on "Water and Water Supplies."

The annual general meeting of the Institute of Hospital Almoners will be held at Caxton Hall, Westminster, S.W., on Friday, March 9, at 5.30 p.m., when Sir William Beveridge will give an address.

Prof. David Brunt, Sc.D., F.R.S., will deliver an address on "Climate and Human Comfort" before the Royal Institution, 21, Albemarle Street, W., on Friday, March 9, at 5 p.m.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* there were 3,098 more cases of measles than in the previous week, and 81 more of dysentery. Whooping-cough, scarlet fever, and diphtheria, on the other hand, dropped in incidence—by 123, 109, and 35 cases respectively.

Diphtheria notifications fell most markedly in the north. Local notifications of whooping-cough fluctuated, and the only large variation was a fall of 59 in Lancashire. The incidence of measles rose sharply in most areas, increases being recorded as follows: Yorks West Riding 880, Surrey 314, Middlesex 251, London 192; Yorks East Riding 152, Durham 127, Cumberland 116, Lincolnshire 103, Lancashire 103; the only decline of any size was in Warwickshire, where 169 fewer cases were recorded.

There were two fresh outbreaks of dysentery during the week: 32 cases were recorded in Cambridge M.B., and 22 in Bath C.B.; 56 cases were reported from the outbreak in Buckinghamshire, Aylesbury R.D. Other large returns were London 45, Essex 43 (Southend-on-Sea C.B. 35), Yorks West Riding 27, Lancashire 26, Gloucestershire 20, Northumberland 15, Middlesex 13.

In *Scotland* the measles incidence fell by 80, diphtheria by 39, and scarlet fever by 19. Diphtheria notifications were at the lowest level in recent months. There were 25 more cases of dysentery than last week; the chief outbreaks were Glasgow 26, Stirling 23, Edinburgh 11, Lanark County 11.

In *Eire* notifications of diphtheria fell for the fourth consecutive week, and the 83 cases marked the lowest total of recent months. An outbreak in Dublin, Clifden R.D. 16, accounted for the rise in the incidence of measles.

In *Northern Ireland* notifications of measles continued to drop; during the past five weeks the weekly total has fallen from 281 to 139. A small rise in scarlet fever, 13, was reported for the fourth week.

Week Ending February 10

The returns of infectious diseases in England and Wales during the week included: scarlet fever 1,466, whooping-cough 1,516, diphtheria 402, measles 20,627, acute pneumonia 1,449, cerebrospinal fever 94, dysentery 324, paratyphoid 2, typhoid 6. Influenza was responsible for 67 deaths in the great towns.

No. 5

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 3.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (*b*) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

---

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

ANY QUESTIONS?

Hallucinations in Old Age

Q.—*A woman aged 78, with excellent mental and physical family history, has of late developed hallucinations at night time. Men or women or animals appear when ? awake, and when she rises to accost them or drive them away they vanish. Is this a serious condition? By day she is quite well, but has B.P. of 200/96.*

A.—Hallucinations, particularly visual ones, and especially when occurring in a dim light, are an indication of a slight confusional state. In this case this could be adequately accounted for by age and presumable consequent slight organic changes in the brain. But it might also be due to a toxic effect. If bromides are being taken, they would be better omitted and replaced by another sedative; sodium chloride should then be given to displace the bromide from the blood. Otherwise it might be worth trying fairly heavy dosage with nicotinic acid. If neither of these causes is operating, the hallucinations can be attributed to vascular changes, but the prognosis for life and sanity is not much affected. Some deterioration can be expected fairly soon in any case.

Choice of Contraceptive

Q.—*What is the best contraceptive for a woman in the forties who has had two children and has no indications of the onset of the menopause? If you advocate a cervical cap and concurrent use of a chemical contraceptive, would you also give some advice on the fitting and hygienic use of such a contraceptive method? Are the cervical caps supplied in various sizes, as the fit of such a pessary must be an important factor in the success of the method? What length of time should elapse after intercourse before it is safe to remove the cap, and should a vaginal douche be used at the same time?*

A.—In this case, as in any other, the method of choice of contraception will depend upon the degree of security required and the preference of both partners. It is wisest to consider a woman as potentially fertile until a year after her last menstrual period. If a third pregnancy would be no disaster, the use of a contraceptive suppository could be advised. If a high degree of security is requested, either the husband must use a condom or the wife must be taught to use an occlusive cap of some suitable kind—a "cervical" type is actually the one least preferred by experts. It would be beyond the scope of this answer to describe the technique of fitting, and teaching the use of, occlusive caps: this technique, like, say, the choice of ocular lenses, requires tuition and experience. Reference will be found in textbooks, or in Butterworth's *British Encyclopaedia of Medical Practice*. Most authorities instruct a woman to cover the occlusive cap with a spermicidal ointment, and if it is not removed until 8 or 10 hours have passed no douche is necessary, for the spermatozoön cannot survive so long in the vaginal medium.

Sulphanilamide for Burns

Q.—*In what form is sulphanilamide best used as routine treatment for burns in a factory practice?*

A.—In the form of a 3% cream made up with lanette wax, castor oil, and water, as described in the M.R.C. Special Report Series No. 249—*Studies of Burns and Scalds* (2nd paper).

Vitamin D and U.V.L.

Q.—*In certain selected cases of undernourishment, where some additional treatment is obviously indicated, would ultra-violet therapy be desirable in addition to giving vitamin D by mouth?*

A.—The antirachitic properties of the appropriate ultra-violet radiation (2,800 to 3,100 A.U.) are easily demonstrated in both animals and human beings. That their action results from the conversion of ergosterol into vitamin D on absorption can be shown by experiments *in vitro* and *in vivo*. Whether irradiation of the skin by a more extensive light spectrum is more beneficial than the ingestion of vitamin D is not easy to determine. It may, however, be stated that, in the experience of those in charge of departments where light is administered, a large proportion of children who have previously been taking vitamins in adequate dosages, but without striking result, undoubtedly derive benefit from irradiation. Even though no scientific proof is forthcoming to support it, the existence of some additional action of ultra-violet rays on the skin over and above the vitamin D production might be postulated. Although there appears to be no justification for the use of ultra-violet radiation in the absence of indications, or where vitamins by the mouth are having the desired effect, there is no reason why ultra-violet rays should be withheld where vitamins by mouth fail.

Mechanism of Fever

Q.—*Why does the temperature rise in a fever, and why does it stay up? What is the precise physiological explanation of that sudden "gearing up" by several degrees of the heat-regulating mechanism; and why, in the crisis of pneumonia, for instance, should the normal functions of the skin be so dramatically restored?*

A.—In fever due to infection the body's thermostat is set at a higher level, mainly as a result of a raised threshold for heat loss. This is believed to be the result of the action of bacterial toxins on the heat centre or centres; but the reaction is a purposive one, as the biological activities of the tissues are increased by the rise in temperature, whereas the conditions are less favourable for some of the pathogenic micro-organisms. The activity of the leucocytes is increased and antibody production is stimulated. This hypothesis has led to the use of artificial fever in the treatment of a variety of diseases, such as rheumatoid arthritis, subacute bacterial endocarditis, resistant gonorrhoea, and syphilis of the nervous system. The crisis in pneumonia occurs shortly after the appearance in the serum of a positive agglutination reaction for the pneumococcus responsible for the infection, and it is probable, therefore, that a critical fall of temperature is generally due to the neutralization of toxins and the sudden lowering of the threshold for heat loss.

Pain from Crystal Violet

Q.—*In the treatment of an indolent varicose ulcer I have applied once a day a 2% aqueous solution of crystal violet. The patient complains of extreme pain after each application. Is this painful reaction usual?*

A.—Some patients complain of pain when dyes are painted on a raw surface, and in the example quoted, since the reaction is severe, an alternative method of treatment might be considered.

Loa loa Infection

Q.—*Some cases of Loa loa infestation have appeared in Palestine, probably imported by Congo native troops. Mountjoy Elliot considers phenothiazine efficient against Filaria medinensis (Dracunculus). Has phenothiazine been used in cases of Loa loa and with what success? I would also welcome information on the toxic effects of phenothiazine.*

A.—Loiasis is common in the coastal regions of West Africa. No drug in therapeutic dosage has been shown to have any lethal action on the adult worms, which wander more particularly in the subcutaneous tissues. The microfilariae do no harm to the individual, and circulate in the peripheral blood solely for the purpose of infecting the insect host. Their removal, even if procurable by drug therapy, can therefore be only temporary and without benefit to the host unless the adult female worms from which they continuously derive are destroyed. Mechanical removal of these adult female worms when visible, as under the conjunctiva, is the only means so far known satisfactorily to achieve this end. Mechanical removal by gentle intermittent traction, with aseptic precautions, is also the most satisfactory and safe method of getting rid of *Dracunculus*.

Phenothiazine has caused a grave and even fatal haemolytic anaemia in children and is to be regarded as a drug potentially dangerous to man.

Blood-volume Estimation

Q.—*What advantages has the improved Evans-blue method of blood-volume estimation over the older methods employing vital red or Congo red?*

A.—The Evans blue (T. 1824) dye has the following advantages over the older dyes used: (1) The tedious corrections for traces of haemolysis in test or control plasma necessary for red dyes can be eliminated. (2) The dye is very stable and is somewhat less toxic. (3) The dye disappears from the blood stream more slowly. The technique recommended is that of Harington *et al.* (*Clin. Sci.*, 1940, 4, 311), where the dye is extracted into butyl alcohol and thus freed from plasma pigments and opacity.

Disappearance of Keloids

Q.—*I have recently observed the disappearance of post-operative large abdominal keloids in patients suffering from deep jaundice. Have bile acids or salts ever been used as a local application for the removal of keloid?*

A.—No record of an effect of jaundice or bile derivatives on keloids has been noted, but it is known that these lesions sometimes disappear spontaneously.

Bilateral Vasoligature

Q.—*A woman has been told that she must not have any more children for at least five years. The usual methods of contraception have proved distasteful, and the husband inquires if he can undergo any operation to make this possible. Is bilateral vasoligation applicable in this case, and does it interfere with normal sexual relations? Is there any other suitable method?*

A.—The operation of bilateral vasoligature is a simple one which inflicts no hardship on a husband and does not disturb the sexual relationship. The only difficulty likely to be encountered is in finding a surgeon to do it. As the law stands, sterilization is an illegal operation. Most surgeons would consider the advice that the wife should not have a child for at least five years an insufficient reason for carrying out vasoligature. They would say that modern methods of birth control are sufficiently effective to make them the right treatment in such a case.

Repeated Miscarriage

Q.—*A woman miscarried at 3 months on two occasions. Five months after the second miscarriage she consulted me with a history of painless haemorrhage after 10 days' amenorrhoea. On examination the os was tightly closed, the uterus normal in size, but there was a small mass in the right fornix, suspected to be an ectopic gestation. No pregnancy was found on operation, but the right tube was much thickened and bound down with adhesions, probably from a chronic appendix removed in 1937. Both ovaries contained over a dozen retention cysts, each about the size of a pea. The tube was freed, the cysts ruptured, and the abdomen closed. The patient wants to have a baby. What is the cause of the non-rupture of the follicles, and is the prognosis for a future pregnancy good or bad? Is treatment with gonadotrophic hormone of the pituitary of any use in these cases?*

A.—Cystic ovaries of this type are not uncommon and do not necessarily have any pathological significance, but from the description it is not easy to decide the nature of the cysts in this case. The cysts were probably atretic follicles, but since the menstrual cycle was disturbed it seems likely that one or more of them contained functional granulosa or lutein tissue. The presence of numerous small cysts does not inevitably mean that the patient was not ovulating; and it would be of value to know if there was any lutein tissue present at the time of operation.

The causes of follicular atresia—cystic degeneration of corpora lutea and corpora albicantia—and follicular retention cysts are different. If it can be assumed that the cysts in this case were follicular and due to non-rupture of the follicle, then the pelvic adhesions may have been a causal factor. It is considered that old pelvic infection, by thickening the tunica albuginea, interferes with ovulation, giving rise to "sclero-cystic disease" of the ovaries. No matter whether this explanation is correct, there is no doubt that cystic ovaries and pelvic adhesions are commonly associated. In the absence of some such local lesion, then failure of the follicle to rupture is assumed to be due to some disturbance of the pituitary-ovary hormone mechanism normally responsible for ovulation. The exact nature of this is still unknown, but ovulation probably requires successive and integrated action of two pituitary factors: various types of upsets in this gonadotrophic stimulus are postulated as causing cystic ovaries, but they are mainly hypothetical.

There does not appear to be any adequate reason for supposing that the ovarian condition played any part in causing the abortions, but the pelvic adhesions may have done so. Now these have been separated the chances for the next pregnancy may be better. If no other cause for the abortions can be found, the chances of the next pregnancy going to term are reasonably good. The patient should be advised to wait 6 months from the time of operation before attempting to conceive again, and when she does become pregnant should adopt the usual precautions of rest and avoidance of coitus. Vitamin E and twice-weekly injections of 5 mg. of progesterone in the early months might also be given empirically.

For the moment there is no indication to treat the cystic ovaries. They may be of little importance, and in any case may correct themselves spontaneously. If, however, the patient does not conceive again after reasonable opportunities, then premenstrual endometrial biopsy should be carried out to see if she is ovulating. If there is evidence that ovulation does not occur or is infrequent, then treatment with gonadotrophin should be tried, although it is difficult to induce ovulation in women by such means. Serum gonadotrophin (follicle-stimulating) should be given over the first half of the cycle, 400 to 1,000 I.U. intramuscularly every three days for five doses. This could be followed by injections of chorionic gonadotrophin in the second half of the cycle. As an alternative the newer preparation of gonadotrophin with synergic factor could be given. Gonadotrophic hormone therapy, however, should be used with caution, since it is reported as sometimes *causing* "cystic ovaries."

Compensation for Doctor's Illness

Q.—*If a doctor is employed as a house-surgeon, R.S.O., or in any paid appointment, and contracts an illness which can be directly attributed to infection whilst acting in the hospital, is he entitled to compensation for loss of wages during his incapacity? Does the Compensation Act apply to doctors so employed?*

A.—A house-surgeon or the holder of a similar appointment in a hospital is doubtless a "workman," and if his yearly salary is £420 or less he may be compensated under the Acts. He is not, however, necessarily entitled to compensation for the effects of an illness he contracts in the course of his duty. The decided cases make the law very obscure, but, broadly speaking, he has to show some element of accident.

Measles Prophylaxis

Q.—*Will whole blood taken from a parent who had measles in childhood, and given intramuscularly—e.g., into the buttock—to an infant of 18 months at the 6th day after contact, materially abate the subsequent development of measles? What dosage should be employed? Has some statistical or experimental evidence already been published in support of the above procedure?*

A.—Pooled adult serum has been used on a large scale for the prevention or attenuation of measles, and a careful statistical analysis of the results obtained in over 1,000 cases is to be found in the fifth L.C.C. report on measles, published in 1938. The dosage of adult serum recommended there is in c.cm. the age of the child multiplied by 4. Thus for this child of 1½ years the dose of adult serum (to be given intramuscularly) would be 6 c.cm., or if whole blood is given, 12 c.cm. Complete protection against measles cannot be guaranteed with adult serum, but does in fact occur in 60 to 75% of inoculated contacts, with attenuation in most of the remainder Children are most susceptible to measles at ages 1 to 3 years, and complete protection at that age could probably be obtained by a rather larger dose—say, 20 c.cm. of whole parental blood. The time after exposure when the blood or serum is given does not greatly matter up to 6 days, but after that time the chances of obtaining complete protection are lessened. Protection should, of course, be the aim in children under 2 years, but in older, healthy children attenuation is preferable, as the child with modified measles is usually immune to further attack, whereas the "protected" child is not. Modification is best obtained by giving half the appropriate dose used for protection within the first 6 days of exposure. Adult serum for use in measles contacts may be obtained in many areas through the local M.O.H.

Psychiatry in the Services

Q.—*As medical officers on the Western front, we would appreciate a practical and simple explanation of the differences between: (1) anxiety neurosis, (2) hysteria, (3) battle fatigue, (4) lack of moral fibre. The differences seem tenuous, but the methods of disposal between the first three and the last vary.*

A.—This is a difficult request to meet. To give an adequate explanation would demand a series of lectures covering most of the field of the psychoneuroses. We cannot expect in psychiatry such clear dividing lines as we find in "organic" medicine; the various syndromes tend to merge into one another, and "mixed states" are common. The main difficulty, however, about this list of four diagnoses is that it is a mixed classification. The names of (1) and (2) imply criteria of symptomatology and psychopathology, and the name of (3) refers to symptoms and aetiology; (4), on the other hand, is essentially a moral judgment.

The term "anxiety neurosis" is applied nowadays to an uncontrollably anxious frame of mind, recognized by the patient as excessive for the circumstances, and usually associated with lack of concentration, easy fatigability, and impairment of sleep and appetite, with physical concomitants such as tachycardia, gross sweating, etc A case of anxiety neurosis may have a superadded hysterical symptom, but the diagnosis "hysteria" is usually confined to men who, because of the nature of their special type of basic personality, under stress convert all, or almost all, their anxiety into "functional" symptoms such as blindness, deafness, aphonia, stammer, headache, or paralysis of a limb, their conscious state of mind remaining unanxious or even nonchalant.

The term "battle fatigue" is a convenient one to use in the case of men of good physique and good previous morale who, under the long-continued stress of exposure to danger, overwork, and insufficient sleep, gradually develop a state of anxious weariness that gives the general impression of being due to mental and physical exhaustion. Such men sometimes have to be ordered to "go sick" before they will do so. It is characteristic of them that, if free from severe depression and if given, at an early enough stage, a period off work with good food, full rest, and adequate sedation, they quickly make a good (or fair) recovery, and willingly return to duty.

Psychiatry, of course, includes within its field not only signs and symptoms in the ordinary sense but all acts of behaviour and attitudes of mind; it attempts objectively to work out the causation of the acts and to assess the significance of the attitudes. The same behaviour and attitudes can be assessed by other criteria, such as their compatibility with the immediate demands of the particular social group in which the patient finds himself at the relevant time. Such criteria loom large in wartime, and especially as regards the behaviour of men on active service. They may, in certain circumstances, be held to have overriding importance, the medical and psychiatric aspects of the case remaining true but being regarded as outweighed.

When a man is considered to be displaying unwillingness to do his duty and to be surrendering to his fear, it is sometimes said that he is showing "lack of moral fibre." The intention of the statement is presumably to keep in the foreground certain urgent practical issues, and possibly to strengthen the resolve of the men remaining on the station. The accuracy and long-term effectiveness of such a statement may by some be thought disputable. In any case, it is important to emphasize that the term "lack of moral fibre" is not a medical diagnosis. It lies outside the scientific field of medicine and psychiatry, and within the pragmatic field of military discipline. The term seems to indicate that the man in question is regarded as a coward, lacking in "guts," will power, and unselfishness; or, at least, that the circumstances demand that he be treated as such. As medical men we may be inclined to think that the patient is a hypersensitive person who more quickly than is normal develops anxiety and complains of it. We may feel that his whole life history reveals poor opportunities of developing a sense of social duty. We may find evidence that the general morale of his particular section is rather low. Possibly, it will seem that factors of all these three kinds play a part.

It would be less difficult to deal with this question if medical officers could stick to their last, reporting after examination on the *medical* aspects of the case, and leaving the use of the term "lack of moral fibre" to the executive authorities.

LETTERS, NOTES, ETC.

Sprouting Legumes

Dr. J. Gee-Tseh Mar (Manchester) writes: Bean-sprouts have been eaten by the Chinese from time immemorial, and may be found on the menus of their restaurants, even in this country. Space does not permit details, but here are a few further points from their technique. (1) Chinese green beans the size of match-heads are used. These have a moderate rate of growth, and the tiny softened cotyledons are easier to chew and digest. (2) Wooden containers retain moisture better than metal ones, so a bucket or keg is ideal. Two or three 1/2-in. holes in the bottom are sufficient for drainage, the beans being kept in by lining the bottom with a piece of matting. (3) Water twice daily with lukewarm water (in this climate), and drain well to prevent the bottom beans from rotting. (4) Cover loosely with matting or a wooden lid to prevent green leaves. Place in a warm dark place. (5) Vary the temperature of the water and surroundings according to experience. Too rapid growth produces tough, weedy shoots with long leaves, and overheating produces brownish rot. Aim at fat, stubby, succulent shoots about an inch long, and taking about a week to grow. (6) When ready, place the sprouts in a loose wire strainer, and gently swish in a basin of cold water. This separates the now black husks, leaving the snowy white shoots. Recently the American magazine *Life* printed an excellent article on methods of cooking bean-sprouts.

Use of Sulphonamide Pastilles in the Oral Cavity

Mr. Henry J. Murphy, M.B., B.D.S., writes from Dublin: For some years I have been using sulphonamide preparations for various conditions in the mouth. Most of the treatments are routine and known to most dentists and doctors, but there is one type of therapy from which I am getting very good results and which I think is little used. I got a pastille made up in a gelatin base containing approximately 2 grains of sulphapyridine and flavoured with menthol. After I extract teeth or do any oral operation I put the patient on these pastilles in the following way. He is to place one in his mouth and allow it to dissolve as slowly as possible (most patients can make the pastille last from half to three-quarters of an hour). I give one pastille immediately after the operation and then fit them into the daily dosage of one pastille on awaking in the morning, two at equal intervals between breakfast and lunch, two at equal intervals between lunch and dinner, one between dinner and bedtime, and one last thing at night. After a severe operation such as extraction of all the teeth I would give two extra tablets the first and second days to make the intervals shorter. I keep up this routine for four days and then reduce the dosage to four pastilles divided equally over the day. I don't syringe the sockets or advise mouth-washes, except when necessary to clear food particles out of the wounds. I find the action of these pastilles and the saliva a more perfect healing stimulus than any other treatment; pain is reduced to a minimum and healing is clean and rapid. I get no gross sepsis or dry sockets after teeth extractions. There will be some pain and swelling, but this is in relation to the trauma caused by the operation and the amount of sepsis of the teeth. I find that whatever infection is present rapidly clears up without the complication of more infection being added from mouth bacteria, and that this healing of the infected areas is as painless and rapid as the body tissues can accomplish it. Before I took to the pastilles I used to break a tablet of sulphapyridine into four equal parts; the quarter tablets gave good results but dissolved faster and therefore would not give as even a distribution of the drug as my present pastille. The dosage of the sulphonamide is big enough to combat the bacteria in the area and still not large enough to have any serious effect on the patient, such as large doses taken orally will sometimes cause.

Effects of Sexual Continence

Dr. A. D. McDwyer (Dublin) writes: The answer to the query on the effects of sexual continence (Jan. 13, p. 67) omitted a fact which, however unfamiliar, is very pertinent to this subject. It has been demonstrated by seminal vesiculography in a series of normal males that the seminal vesicles in the absence of emissions, involuntary or otherwise, completely and gradually empty per urethram over a period of approximately 40 days (*Med. Annu.*, 1937, John Wright and Sons, Bristol). Consequently it seems that the seminal fluid is not normally retained. Secondly, a spontaneous and involuntary ejaculation during sleep is not, of necessity, a normal mechanism to prevent the retention of semen in completely continent males. Since Nature has provided for complete continence it seems illogical to impute various vague ills and psychological upsets to chastity *per se*. No ill effects result from such a state in a normal male.

Treatment of Varicose Ulcer and Eczema

Dr. R. R. Foote (London, W.1) writes: Under this heading (Jan. 6, p. 26) Dr. M. Ghosh does a great service in calling attention to the use of elastic web bandage as a substitute for the almost universal use of elastic adhesive bandage. His reasons for discarding the latter are that many cases are allergic to the constituents of the bandage, that haemorrhages of ulcers may occur under it, and that these bandages are, anyway, difficult to obtain. He might have quoted Dickson Wright, that it is harder to apply an elastic adhesive bandage *correctly* than it is to remove a gall-bladder! I would like to add to Dr. Ghosh's suggestions for treatment the use of crude coal tar for his eczematous cases, the application of Unna's plasters according to the technique of Dickson Wright, and the use of the "ceraban" bandage. I feel that Dr. Ghosh's 100% success with 112 cases would not remain at this high level unless he availed himself of these suggestions.

Oxalated Blood for Cell Counts

Dr. G. J. W. Ollerenshaw (Sunbury-on-Thames) writes: I would like to support Dr. Martin Folan's letter (Jan. 13, p. 70) with regard to the use of oxalated blood specimens for cell counts. In my experience one can obtain a very high degree of accuracy (as compared with specimens collected at the same time and counted immediately without the addition of an anticoagulant), provided the oxalated specimen is examined within 24 hours of collection. As Dr. Folan points out, if a smear is made when the blood is collected a full blood count can be performed. The quantities used in this work here are 3 c.cm. of venous blood with the addition of 0.5 c.cm. of the following mixture: 1.2 g. ammonium oxalate; 0.8 g. potassium oxalate; 100 c.cm. distilled water, with the addition of 1 c.cm. 40% formalin. We are about to introduce a modification, which should be even more satisfactory, by drying this solution on to the walls of the specimen tube in an oven prior to dispatch.

Infected Foci in Blood-stream Infections

Dr. Sydney Pern (Ballarat, Victoria) writes: The *Journal* for Sept. 16, 1944 (p. 380), contains a reference to penicillin in bacterial endocarditis. It also mentions that in spite of the blood becoming sterile the patient relapsed. I would like to make the following suggestions. In blood-stream infections the micro-organisms have to gain entrance from some site—such as tonsils, infected sinuses, pyorrhoea, apical abscesses, etc.—and just so long as these infected foci are left so will the organisms continue to invade the blood stream. It is a very moot point if organisms are able to breed and multiply in the blood stream, so the obvious conclusion is that they are pouring in from outside. I have not yet heard of anybody attempting to remove any of the foci of infection in these desperate cases, yet it would appear the most logical procedure to adopt. I hope that somebody will have the temerity to try.

CROSS-INFECTION RISKS IN THE HOSPITALIZATION OF MEASLES PATIENTS*

BY

JOYCE WRIGHT, D.M.

(From the L.C.C. North-Western Hospital and Group Laboratory, Hampstead)

A mild catarrh of the aural mucous membranes, due to primary virus infection, is not unusual in the eruptive stage of measles. The serious and permanently damaging conditions, of which suppurative otitis media is the most common, are caused by secondary invading organisms, particularly the haemolytic streptococcus and the pneumococcus. The perforated drum may heal and no further trouble ensue; on the other hand, infection may spread to the mastoid process, the meninges, or the brain. A report by Linford (1936) on the otological examination of 400 unselected measles patients in an L.C.C. fever hospital illustrates the extensive ear damage which may occur. Of these patients 56 (14%) developed otorrhoea, 35 (9%) severe otitis media, 204 (51%) mild otitis media; while 105 (26%) remained normal throughout. Among 100 unselected patients suffering from measles otorrhoea, one developed facial paralysis; one facial paralysis, extradural abscess, and mastoiditis necessitating operation; four required unilateral mastoidectomy; and 12 suffered appreciable destruction of the tympanic membrane.

That haemolytic streptococci may spread in measles wards as a secondary transmissible disease superimposed on the primary virus infection was shown by Allison and Brown (1936). They found that among 43 patients admitted to a measles ward 51% became cross-infected by haemolytic streptococci and that as a result 19% of the 43 patients developed otorrhoea. Wright, Cruickshank, and Gunn (1944) confirmed the findings of Allison and Brown and suggested that dust particles derived from bed-clothes and garments are possibly the chief means by which streptococci spread in measles wards.

Scope of the Investigation.—The present report falls into two sections: (A) A detailed study, with bacteriological examination and clinical observation, of the measles patients in one ward for 12 weeks in March, April, and May, 1943. This ward served as a control in the experiment reported by Wright *et al.* (1944). (B) An analysis of the case histories of all measles patients admitted to the North-Western Hospital from Dec. 1, 1942, to May 31, 1943.

Investigation A

Ward Arrangements.—(1) The normal bed complement of the ward was 18 and the normal bed-spacing 12 feet between bed-centres. During the 12 weeks of the investigation two extra beds and during two weeks four extra beds were put up, with a corresponding reduction of bed-spacing. (2) Sulphonamides were given prophylactically to all patients unless there was any contraindication. During the first three weeks of the work a number of different drugs were used, in varying doses and for varying times. An intensive scheme was then introduced and alternate patients admitted to the ward received sulphanilamide or sulphathiazole. The dosage, according to age, was 1 to 2 g. on admission, 3 to 7.5 g. daily for 3 days, followed by 1.25 to 3.75 g. daily until the day before discharge. (3) On admission prophylactic mixed scarlet fever and diphtheria antitoxin was injected into 54 (70.1%) of the 77 patients admitted. (4) Mattress, pillows, and blankets of each patient were disinfected in the hospital disinfector (5-lb. pressure for 30 minutes) on his discharge or transfer from the ward. (5) Four patients with middle-ear suppuration remained in the ward until discharged and were barrier-nursed. Other patients with otitis media were removed to isolation elsewhere in the hospital.

Routine Procedure.—At the start of the investigation nose and throat swabs were taken from all patients in the ward. Subsequently swabs were obtained from the nose and throat and from any suppurative lesion—e.g., ear discharge, impetigo—of every new patient immediately *before* admission to the ward and then once weekly. Nose and throat swabs were taken from each member of the ward staff once monthly, and also on development of any upper respiratory tract infection. Swabs were plated on gentian violet blood-agar plates and incubated aerobically for 18 hours at 37° C. Representative colonial forms of haemolytic streptococci were tested for their serological type by the Griffith agglutination method. Cross-infection was judged to have occurred if a patient, free from haemolytic streptococci on admission, acquired these organisms in the nose or throat; or if a patient who carried haemolytic streptococci on admission acquired haemolytic streptococci of different type in the nose or throat. In assessing the cross-infection rate the Type 6 streptococcus was adopted as the "indicator organism," since more than 90% of the cross-infections were due to this type. For completeness, however, cross-infections with other types are recorded.

Complication Rate.—A daily round of all patients in the ward was made and any complication or rise of temperature noted. Appropriate swabs were taken and plated on blood agar, and/or gentian violet blood agar, and/or tellurite medium, according to the nature of the complication. Ear and mastoid swabs were investigated for the presence of haemolytic streptococci, pneumococci, staphylococci, and diphtheria bacilli. Any haemolytic streptococci isolated from patients with complications were tested for serological type.

Results of Investigation A

Cross-infection Rate.—At the start of the investigation 8 (36.4%) of the 22 patients in the ward had Type 6 streptococci in the nose and/or throat; one patient had Type 2 and one Type 27 streptococci. During the ensuing 12 weeks 47 (72%) of the 65 patients at risk acquired Type 6 streptococci in the nose and/or throat. One patient acquired Type 2 and one Group C streptococci.

Of the 47 cross-infections of the upper respiratory tract 21 (44.7%) occurred within the first week of hospitalization, and 16 (34%) in the second. The average day on which cross-infection was discovered was the 10th, with a range from the 3rd to the 34th. (The date on which the cross-infection actually occurred may have been earlier than the date on which it was discovered, as swabs were not taken until the routine weekly swabbing day unless there was clinical evidence to suggest cross-infection.) In 30 instances the cross-infecting Type 6 streptococcus was first discovered in both nose and throat at the same swabbing, in 8 in the nose only, and in 7 in the throat only. In most of the "positive" patients the streptococci were present in abundance.

Among children under the age of 9 years the cross-infections were fairly evenly distributed as to age group. Of 38 patients under the age of 3 years, 29 (76.3%) became cross-infected with Type 6 streptococci; of 14 from 3 to 5 years, 9 (64.3%); and of 9 from 6 to 8 years, 8 (88.9%). Of the 4 patients of 9 years or over, only one acquired Type 6 streptococci.

---

* A report to the Medical Research Council.

Complications

Middle-ear Suppuration.—Of the 65 patients exposed to risk, 12 (18.5%) developed middle-ear suppuration due to Type 6 streptococcal cross-infection; 4 of this number required mastoidectomy, and Type 6 streptococci were in each case recovered from the mastoid. Six of the 12 patients had some history of previous ear infection, but 5 of these were free from otorrhoea on admission, and the 6th, admitted with otorrhoea, had no haemolytic streptococci in the ear discharge. Histories obtained at the home are not necessarily reliable; they suggested, however, that children with previous ear infection are particularly liable to develop ear complications if cross-infected. Six typical histories are as follows:

H. A.: 1 year 11 months.—Admitted March 5, 1943, with uncomplicated measles. 1st day, no h.s. (haemolytic streptococci) in nose or throat. 6th day, few Type 6 h.s. in nose. 13th day, fair number Type 6 h.s. in nose and throat. 17th day, right suppurative otitis media; abundant Type 6 h.s. in ear discharge. 65th day, left hospital.

D. B.: 1 year 2 months.—Admitted March 12, 1943, with measles and bronchopneumonia. 1st day, no h.s. in nose or throat. 6th day, right suppurative otitis media; abundant Type 6 h.s. in nose, throat, and ear discharge. 34th day, left hospital.

C. D.: 1 year.—Admitted March 16, 1943, with uncomplicated measles. 1st day, no h.s. in nose or throat. 7th day, abundant Type 6 h.s. in nose. 17th day, right suppurative otitis media; abundant Type 6 h.s. in ear discharge; gastro-enteritis. 23rd day, child extremely ill and dehydrated. 24th day, bilateral mastoidectomy; abundant Type 6 h.s. in both mastoids; extensive disease with necrosis found on both sides. 68th day, rubella. 86th to 95th day, boils of forehead and abdomen. 130th day, left hospital.

N. H.: 7 years.—Admitted April 4, 1943, with uncomplicated measles. 1st day, no h.s. in nose or throat. 7th day, abundant Type 6 h.s. in nose and throat. 8th day, right suppurative otitis media; abundant Type 6 h.s. in ear discharge. 39th day, left hospital.

T. R.: 6 years.—Admitted March 28, 1943, with measles. History: otitis media on previous day; otorrhoea at 1½ years. Examination on admission: old perforation of right drum; no right or left otorrhoea. 1st and 10th days, no h.s. in nose or throat. 14th day, left suppurative otitis media; abundant Type 6 h.s. in ear discharge. 15th day, pustules on hands and feet; abundant Type 6 h.s. in pus. 54th day, left hospital.

B. P.: 10 months.—Admitted March 5, 1943, with measles. History: ear discharge on previous day. Examination on admission: no right or left otorrhoea. 1st day, no h.s. in nose or throat. 6th day, abundant Type 6 h.s. in nose and throat. 8th day, right purulent conjunctivitis; abundant Type 6 h.s. in eye discharge. 18th day, left mastoidectomy; left extradural abscess of middle fossa; abundant Type 6 h.s. in mastoid. 76th day, left hospital.

The average day of onset of suppurative otitis media was the 15th hospital day, with a range from the 6th to the 30th. In three of the 12 patients the onset of Type 6 streptococcal cross-infection and consequent otorrhoea occurred within the first week in hospital. This finding disproves the common belief that otorrhoea which develops within the first week in hospital is due to pre-existing infection. In addition to these 12 patients, two of the 8 patients who harboured Type 6 streptococci at the start of the investigation later developed suppurative otitis media. Abundant Type 6 streptococci were found in the ear discharges, and it may reasonably be assumed that they had been acquired by cross-infection.

Skin Infections.—Of the 77 patients either present at the start of the investigation or subsequently admitted to the ward, 20 (or 26%) developed infections of the skin. Among the 20 patients there were 26 skin infections: impetigo of face, 13 cases; boils of buttocks, 6 cases; septic fingers or toes, 4 cases; boils of head, abdomen, or anterior auditory meatus, 3 cases. Skin lesions of only 11 of the patients were examined bacteriologically; in seven instances Type 6 streptococci were isolated in abundance and in four cases *Staph. aureus.*

Other Complications.—One child admitted with laryngitis died with bronchopneumonia on the 9th day in hospital. Her nose and throat swabs on admission had yielded no haemolytic streptococci. From her larynx and pharynx at necropsy Type 6 streptococci were isolated, and these organisms may have contributed to her death. Five children developed bronchopneumonia after admission. Two had no haemolytic streptococci in the upper respiratory tract; the other three had Type 6 streptococci in the nose and throat, but it was not determined whether these caused the pneumonia.

Prolongation of Hospital Stay due to Cross-infection

If an allowance of 14 days' stay is made for a normal measles case the excess time spent in hospital by the 14 patients with middle-ear suppuration (additionally complicated in six by skin infections and in one by rubella) amounted to 89 weeks. Excess time spent by the 14 children with skin infections amounted to 40 weeks. Hospital infection among the children admitted to only one ward during a period of 12 weeks led, therefore, to an excess stay totalling 129 weeks.

Investigation B

Investigation A showed by combined bacteriological and clinical examination that a high rate of middle-ear suppuration due to streptococcal cross-infection prevailed in one ward during the spring of 1943. To find out if this occurrence was limited to one ward or to one season, an analysis was made of the middle-ear complications among *all* measles patients admitted to the hospital from Dec. 1, 1942, to May 31, 1943. The analysis was made according to a scheme drawn up in the light of the bacteriological work recorded in Investigation A. The scheme, with reasons where called for, was as follows:

1. The case-history sheets were carefully searched for evidence of complications. (The summary occasionally omits some important complication.)

2. The date of onset of a complication was referred to the month of admission—e.g., a patient admitted in February who developed a complication in March was placed in the February group.

3. All patients suffering from measles on admission to hospital were included; those who developed it after admission were excluded.

4. The day of admission was counted as the first hospital day, even if the time of admission was afternoon or evening.

5. Cases of middle-ear suppuration were classified as follows:—(*a*) *Early:* Present on admission, or developed on or before the 5th hospital day. (*b*) *Late:* Developed on or after the 6th hospital day. Patient was included in series however long the interval between the onset of measles and the onset of the complication, even if a second infection—e.g., chickenpox—had occurred in the meantime. (The division into "early" and "late" was set between the 5th and 6th days because the bacteriological work in Investigation A had shown that streptococcal cross-infection could cause middle-ear suppuration as early as the 6th hospital day—see Case-history D. B. above. All cases of middle-ear suppuration which develop after the 5th day in hospital should be regarded as due to cross-infection unless the contrary can be proved.)

6. All patients with a history of previous otitis media, otorrhoea, or "ear trouble" were included in the analysis. (Evidence from Investigation A suggested that a patient with a history of middle-ear infection is more liable than others to suffer from the consequences of cross-infection; exclusion of such patients from an analysis, as is sometimes done, leads to an underestimate of the risks of cross-infection.)

Table I.—*Incidence of Early and Late Middle-ear Suppuration (M.E.S.) by Month of Admission and by Age Group*

	Dec.	Jan.	Feb.	Mar.	Apr.	May	Total
Under 3 years:

7. If middle-ear suppuration developed in one ear on or before the 5th hospital day and in the other ear after the 5th hospital day the case was placed in the "early" group.

8. According to this scheme, figures were analysed by age group, by month, and by ward. (*a*) The age groups were: under 3 years, 3 to 5 years (i.e., 3-, 4-, and 5-year-olds), 6 to 8 years, and 9 years or over. (*b*) The months were Dec., 1942, to May, 1943, inclusive. This covered the epidemic period in London.) (*c*) Analysis by wards depended on admission to the ward at the onset of measles; any subsequent transfer—e.g., to isolation units—was disregarded. A certain number of patients, including 35 of 9 years or over, were admitted and nursed throughout in isolation accommodation. These were not included in the ward analysis.

The following points emerge from the analysis:

1. The total percentage of patients who suffered from "early" middle-ear suppuration was 3.6 and from "late" 13.3, showing how much in excess over the early ear complications were the late ones, due to cross-infection in the wards. (Actually the latter figure would probably have proved to be 1 to 2% higher if in one ward, for 9 weeks, dust-borne infection had not been controlled by means of oil-treated bed-clothes and garments (Wright *et al.*, 1944).) The average hospital day on which late middle-ear suppuration developed was the 14th, with a range from the 6th to the 48th. In 21 cases the complication was bilateral and in 45 unilateral.

2. The percentage of early and late middle-ear suppuration cases in the four age groups was as follows:

	Early	Late	Total
Under 3 years	4·2	14·3	18·5
3 to 5 „	5·8	13·9	19·7
6 to 8 „	0	18·6	18·6
Over 9 „	0	3·2	3·2

The percentage of late middle-ear suppuration cases did not vary greatly in the three groups under the age of 9 years. The figures for the 6-to-8-year group show a particularly marked excess of late complications over early. In this group no child was admitted with otitis media or developed it before the 6th day; but nearly one in every five children was a victim of late middle-ear suppuration, presumably due to cross-infection. The percentage incidence of middle-ear suppuration was considerably lower in patients of 9 years and over. This would be due partly to increased resistance and partly to reduced exposure to infection, since nearly 60% of the patients of this group were nursed in isolation accommodation.

3. The percentage incidence of early and late middle-ear suppuration by month was as follows:

	Early	Late	Total
Dec., 1942	2·2	19·6	21·7
Jan., 1943	3·1	10·4	13·5
Feb., „	1·6	18·7	20·3
March, „	4·7	14·9	19·5
April, „	4·5	6·0	10·5
May, „	8·3	2·8	11·1

During December and February the high rates of 19.6 and 18.7% were recorded for late middle-ear suppuration. If the less susceptible group of "9 years and over" is omitted, the incidence for these two months becomes 21.4 and 20.4% respectively. The late middle-ear suppuration rate was less among patients admitted in April and May than among those who were admitted in the winter months.

4. The percentage incidence of late middle-ear suppuration cases in the three open wards of the hospital were: Ward A, 18.8%; Ward B, 17.2%; and Ward C, 12.9%. The highest rate was in Ward A, the figures for which were given in detail in Investigation A. The lower figure for the identical ward —Ward C—was largely accounted for by the fact that during a period of nine weeks the cross-infection rate was reduced by the use of oil-treated bed-clothes and garments. If for this period the figures for Ward A are substituted for those of Ward C, the correct percentage for the whole period of 6 months for Ward C becomes 17.9. Wards A and C were of an old-fashioned type, but this apparently was not the factor responsible for their high complication rate, since the rate was nearly equalled by that of Ward B, an "open" ward of the ordinary fever hospital pattern.

Table II shows how the remote effects and serious consequences of cross-infection fell most heavily on the children under 3 years of age. In this group of 238 children, 11 (4.6%) underwent mastoid operations—i.e., nearly one-third of the 34 who developed late otorrhoea. Among the total number of 496 measles patients admitted to the hospital, 14 required mastoidectomy; of these, 11 (78.6%) were under 3 years of age. Gastro-enteritis attacked three of these young children; one died as a result.

TABLE II.—*Complications following Late Middle-ear Suppuration*

Case	Age in Years	Day of Onset of Otorrhoea	Day of Onset and Particulars of Further Complications
1	2 9/12	15th, right otorrhoea	51st, scarlet fever
2	5 6/12	14th, left „	24th, „ „
3	9/12	24th, bilateral „	32nd, retropharyngeal abscess
4	1 4/12	17th, left „	69th, gastro-enteritis 78th, bilateral mastoidectomy 84th, death
5	8	6th, right „	23rd, right mastoidectomy 30th, impetigo of face
6	2 4/12	15th, „ „	15th, left mastoidectomy
7	10/12	17th, „ „	20th, left mastoidectomy and extradural abscess
8	1	17th, „ „	17th, gastro-enteritis 24th, bilateral mastoidectomy
9	5/12	9th, „ „ 10th, left „	15th, gastro-enteritis „ bilateral mastoidectomy
10	2	7th, right „	10th, „ „
11	1 2/12	21st, „ „ 22nd, left „	23rd, „ „
12	3	8th right „	94th, right mastoidectomy
13	5	8th, „ „ 10th, left „	75th, „ „
14	1 10/12	30th, right „	32nd, bilateral mastoidectomy
15	7/12	6th, „ „	8th, orbital cellulitis 15th, bronchopneumonia 21st, extensive pemphigous eruption 86th, right mastoidectomy
16	2 6/12	18th, bilateral „	35th, right suppurative parotitis
17	2 6/12	29th, left „	45th, left mastoidectomy
18	1 6/12	11th, „ „ 17th, right „	35th, bilateral mastoidectomy

Forty-five infants under 1 year of age were admitted with measles; the incidence of 13.3% for late middle-ear suppuration among them was no higher than that among children of other age groups. Of the 6 infants who developed late otorrhoea, however, four suffered very serious further complications—namely, retropharyngeal abscess (one case), extradural abscess and mastoidectomy (one case), bilateral mastoidectomy and gastro-enteritis (one case), and orbital cellulitis, bronchopneumonia, and right mastoidectomy (one case).

Prolongation of Hospital Stay due to Late Middle-ear Suppuration and its Sequelae.—Allowing 14 days as the normal stay in hospital for an uncomplicated measles case, the excess time spent by the 66 patients with late middle-ear suppuration and its sequelae amounted to 432 weeks. At an average weekly cost of £5 per patient, the extra expense for these patients, detained in the main as a result of cross-infection, would amount to £2,160.

Discussion

The prevention of middle-ear complications in measles is important for two reasons: (*a*) Suppurative otitis media in young children is liable to cause permanent impairment of hearing. Kerridge (1936) found in a London special school that the starting-point of deafness among 18% of the children was a specific fever, and that, among the fevers causing deafness, measles led with a figure of 43%. (*b*) The high measles attack rate during each epidemic results in large numbers of young children being exposed to the risk of ear infection.

In Investigation A bacteriological and clinical observations were made over the same period in one ward. The results showed that where middle-ear suppuration developed after admission to hospital it was in the great majority of cases due to streptococcal cross-infection. It demonstrated, further, that complications due to cross-infection may occur sooner than is commonly supposed—namely, as early as the 6th hospital day. Banks (1944) stated that the high figures presented in Investigation A were apt to give a false impression of the magnitude of the problem. The figures of Investigation B show, however, that a high incidence of measles otitis media prevailed in all three "open" wards of the hospital from the beginning of December to the end of March. Whether the incidence of ear complications in this hospital was higher than that in others it is impossible to say, as no comparable figures have been published. Accurate comparison of the figures for different hospitals would require the undertaking of analyses in accordance with an inflexible scheme such as that drawn up in Investigation B. Otherwise it is possible that in some hospitals (*a*) the figures for measles otitis media may be estimated after the exclusion of patients with a history of previous ear trouble, (*b*) the dividing day between "early" and "late" otitis media may differ. In interpreting the results of "short-stay" hospitals it should be taken into consideration that patients may develop complications, due to hospital infection, after returning home. It is important that any analyses made should be undertaken by medically qualified persons and not by clerical staff.

The dangers of hospitalizing measles patients are clearly stated in the L.C.C. Report on the Measles Epidemic of 1931–2: "Measles is not a disease which lends itself to mass treatment, and is not very suitable for hospital treatment for various reasons. . . . If the home conditions are suitable, it is better for the patient to be treated at home, where, if medical assistance is available and the child is put to bed in a well-ordered, well-ventilated, and airy room, there need be no risk of complications." The figures presented in this paper show that the risk of serious complications due to hospital life are still present. Nevertheless, during every epidemic the fever hospitals of London are flooded with measles cases. The comparative risk of infection by haemolytic streptococci in a hospital or in a home may be shown by a few figures. In a measles ward each patient may be exposed to 20 fellow-patients, over 60% of whom may be carriers of streptococci of epidemic type in profuse numbers; to 10 staff members, one or two of whom may be streptococcal carriers; to infected dust particles in the air; and to grossly contaminated ward articles and toys. In a home a measles patient has a good chance of not encountering any haemolytic streptococci at all. Home visiting by doctor and nurse is best for the treatment and nursing of uncomplicated measles. After over five years of war, home nursing is not always practicable; but the fact remains that too many patients whose circumstances would permit home nursing are without due inquiry taken into hospital. So far as is possible measles patients who can be cared for at home should remain at home, and hospital accommodation be reserved for those who are actually in need of hospital care. For the protection of those patients who must be admitted to hospital certain recommendations may be made in the light of the findings of Investigations A and B.

Recommendations for the Nursing of Measles Patients in Hospital

(*a*) *Avoidance of Overcrowding.*—A distance of 12 feet between bed-centres should be strictly adhered to. In the long run no economy in accommodation or staff is gained by overcrowding; since this leads to complications which in turn prolong the average stay in hospital.

(*b*) *Protection of the Most Susceptible Groups.*—Infants under 1 year of age incur the highest risk of serious complications due to cross-infection, and should accordingly be given priority of isolation accommodation. The next claimants to special consideration are children of any age with a history of previous otitis media, because they are particularly susceptible to further attacks.

(*c*) *Preventing the Entry of Haemolytic Streptococci to the Ward.*—Patients with a suspected haemolytic streptococcal infection should be nursed in isolation units until they are proved to be free from streptococci. Patients should not be moved direct from one open ward to another open ward, since by so doing an epidemic streptococcal strain may be spread.

Patients under (*b*) and (*c*) for whom isolation accommodation cannot be found should be barrier-nursed in the open ward. In making the analysis for Investigation B it was found that 29 patients over 18 years of age were nursed in isolation units. Since adults run little risk of cross-infection they should not, for reasons of their comfort alone, be allocated to accommodation required for the protection of infants and children.

(*d*) *Control of Dust-borne Infection.*—Blankets, sheets, pillow-slips, and patients' garments may be treated with technical white oil during the laundering process. The method of Harwood, Powney, and Edwards (1944) is practicable in a well-conducted hospital laundry. This recommendation rests on the marked fall in cross-infection which followed the introduction of oil-treated articles into a highly contaminated measles ward, and on the inference that dust is an important means of streptococcal spread (Wright *et al.*, 1944). If oiling of bed-clothes is not practicable, bed-making rounds should be abolished and the beds made individually as required, with the least possible disturbance. This avoids a sudden large increase in aerial contamination. Beds should preferably be made during hours of good ventilation and not during "dim-out" hours. Floors, if of wood or covered with linoleum, should be treated with spindle oil (see M.R.C. War Memorandum No. 11, Appendix E). Children should not be placed on the floor or on a blanket on the floor, as is sometimes done while beds are being made or when convalescents are playing.

(*e*) *Control of Contact Infection.*—*Nasal toilet*:—In Investigation A it was found that in doing the nasal toilets the nurses' fingers and the vaseline became contaminated, often heavily, with the prevalent Type 6 streptococci. The procedure was to clean the nostrils with cotton-wool rolled at the bedside on to orange sticks and then to smear the face with vaseline; streptococci were thus implanted direct into the nose and on to the face. Individual equipment consisting of previously prepared sterile cotton-wool pledgets on orange sticks, individual vaseline-pots, and discard jars should be provided at each bedside. Nurses should wash their hands each time after attending to a patient's nasal toilet. This is important in preventing the spread of impetigo as well as respiratory infection. *Bedpans and chamber-pots*:—These should be disinfected between each use (see M.R.C. War Memorandum No. 11, Appendix A). *Mugs, spoons, and forks*:—These articles should be boiled between each use. *Dressings*:—The "no-touch" technique should be followed (see M.R.C. War Memorandums No. 6 and No. 11, Appendix D). Discharging ears should be covered, and pus should not be allowed to run on to pillows and bed-clothes. *Toys and books*:—These proved a prolific source of haemolytic streptococci. In measles, which normally is a short-stay fever, children will suffer no undue hardship if they are denied toys and books. *Barrier-nursing*:—This should be immediately introduced for any patient who develops, or who is under suspicion of, an intercurrent infection of the respiratory tract, gastro-intestinal tract, or skin. If isolation accommodation is not available for such a patient, barrier-nursing should be maintained until bacteriological investigation proves him to be free from infection.

(*f*) *Control of Droplet-borne Infection.*—All members of the staff should wear masks while attending to measles patients. The fact that masking is enforced in bed-isolation wards indicates that it is not impracticable in measles wards. Staff members who develop upper respiratory tract infection should immediately be taken off duty and should not nurse measles patients until they have fully recovered.

(*g*) *Convalescent Patients.*—The control of convalescent measles patients provides a difficult problem. The risk of their becoming cross-infected is high unless strict measures are taken for their protection. The procedure which is followed in bed-isolation wards should be adopted—i.e., the patient when up should be restricted to his own bed-area and should not be allowed to gather with others at a meal-table or round the fire.

(*h*) *Chemoprophylaxis.*—Prophylactic sulphonamide administration has been advocated by Banks (1944); he did not, however, include a control group among patients of the same epidemic. That chemoprophylaxis is not necessarily an effective measure is shown by the high cross-infection and complication rates at the North-Western Hospital among patients who received, as a routine, sulphonamides in high dosage throughout their stay. In two wards the epidemic Type 6 streptococcus was found by *in vitro* tests to be sulphonamide-resistant (Wright *et al.*, 1944). Discrepancies in the evaluation of chemoprophylaxis in measles are possibly due to varying degrees of sensitivity and resistance of the particular streptococcal strains involved. Prophylactic sulphonamides are not always effective, they involve the risk of engendering drug-fast strains, and they are time-consuming and worrying for he nursing staff to administer. For these reasons it is probably wiser to reserve sulphonamides for therapeutic purposes.

Summary

The results are recorded of two investigations made among measles patients admitted to the North-Western Hospital during the epidemic of 1942–3.

1. In Investigation A an intensive study of the bacteriological and clinical conditions in one ward for a period of 12 weeks showed hat: (*a*) 72% of the 65 patients at risk became cross-infected with Type 6 haemolytic streptococci; (*b*) as a result of Type 6 streptococcal cross-infection 12 patients (18.5%) developed middle-ear suppuration—of these 12, 4 underwent mastoid operations; (*c*) 26% of the patients developed skin infections, mainly impetigo; (*d*) allowing 14 days as the normal stay for an uncomplicated measles case, excess stay in hospital amounted to two and a half years.

2. In Investigation B an analysis was made, in accordance with a set scheme, of the middle-ear-suppuration cases among all the measles patients admitted to the hospital from Dec., 1942, to May, 1943, nclusive. This showed that: (*a*) Among the 496 patients 3.6% suffered from "early" (i.e., on or before the 5th hospital day) middle-ear suppuration, and 13.3% from "late" (i.e., on or after the 6th hospital day). In view of the findings in Investigation A, it could be assumed that the great majority of the late middle-ear complications were due to cross-infection. (*b*) Among children under the age of 9 years the percentage incidence of late middle-ear suppuration did not vary greatly in the three age groups. Under 3 years of age the incidence was 14.3%, in the 3-to-5-year group 13.9%, and in the 6-to-8-year group 18.6%. Among patients of 9 years or over the rate was much lower, being 3.2%. (*c*) The late middle-ear-suppuration rate was considerably lower among patients admitted in April and May than among those admitted in the winter months. (*d*) The incidence of late middle-ear suppuration did not vary greatly in the three "open" wards of the hospital, being in Ward A 18.8%, in Ward B 17.2%, and in Ward C 17.9% (corrected igure). (*e*) The percentage incidence of ear complications was not higher among children under 3 years of age, but the seriously damaging effects of cross-infection fell most heavily upon them. Of the 238 children in this group, 11 (4.6%) underwent mastoidectomy, and one of these died. Infants under 1 year of age suffered particularly severely; 6 of the 45 infants admitted to the hospital developed late middle-ear suppuration, and in 4 cases this was followed by further complications—namely, in one by retropharyngeal abscess, in one by extradural abscess and mastoidectomy, in one by bilateral mastoidectomy, and in the last by orbital cellulitis, bronchopneumonia, and mastoidectomy.

3. In view of the high complication rate due to cross-infection, reatment at home rather than in hospital is advocated for patients with uncomplicated measles.

4. For the protection of measles patients who must be admitted o hospital, recommendations are made for the control of cross-nfection and for improvements in administrative and nursing procedures.

I wish to thank Dr. W. Gunn for his advice, and for access to he hospital records; Dr. R. Cruickshank for his unfailing help, and for granting laboratory facilities; Drs. M. B. Alexander and Y. Eiser, the medical officers of the wards; Drs. S. D. Elliott and D. Colebrook for streptococcal typing sera; and the Medical Research Council for a personal grant.

Dorothy M. Horstmann, Robert Ward, and Joseph L. Melnick J. *Amer. med. Ass.*, Dec. 23, 1944, p. 1061) report a study undertaken at the New Haven Hospital, Connecticut, to determine the average duration of excretion of poliomyelitis virus in stools of patients who had had acute infection. The stools were examined of 61 patients in whom a clinical diagnosis of poliomyelitis had been stablished. It was found that 61% excreted virus during the first wo weeks after onset of the disease; 50% during the third and ourth weeks; 27% at the fifth and sixth weeks; 12.5% at the eventh and eight weeks. Between the ninth and twenty-fourth weeks virus was detected in only one of 52 specimens tested; this was excreted by a boy in the twelfth week of paralytic disease. Not one of the 61 patients followed-up was demonstrated to become a persistent carrier of poliomyelitis virus.

CHANGES IN PERSONALITY AFTER CEREBROSPINAL FEVER

BY

M. NARASIMHA PAI, M.B., B.S., M.R.C.P.
D.C.H., D.P.H., D.T.M., D.P.M.

(From a Neuro-psychiatric Centre)

Literature on the neuro-psychiatric residuals and changes in personality after cerebrospinal fever (C.S.F.) is very meagre, and most of the papers on this subject record observations made chiefly on children. Among the papers dealing with adults are 12 English, 4 American, 6 French, 1 Russian, 1 Spanish, and 7 German. There is, however, no unanimity in their findings. Some writers—notably Rolleston and Ronaldson (1940), Rundle (1929), and others—say that a few patients with predisposition to neuroses may during convalescence suffer from neurasthenia and occasionally from mental deterioration (Brain, 1940). Others, including Netter and Debré (1911) and Foster and Gaskell, are emphatic that after recovery from the acute illness and in the absence of internal hydrocephalus no mental changes occur. In 1918 Rosanoff described a uniform syndrome as a result of observations made on 26 adults at the U.S. Army Hospital for War Neurosis at Plattsburg Barracks. The symptoms in order of frequency were limitation of flexion of the spine; undue fatigue; pains in the back, legs, and head; tendency towards dizziness and faintness; muscular weakness; tendency towards blurring of vision associated with photophobia; and, lastly, impairment of appetite and sleep associated with a state of undernutrition. These findings have not been confirmed by subsequent writers.

From a study of patients who gave a history of C.S.F. in adult years one finds that some who have apparently recovered from the acute stage may continue to complain of symptoms which incapacitate them for work for prolonged periods. Some of them wander from hospital to hospital, and on account of negative findings are finally labelled "neurotics," which only adds to their hardship by depriving them of the sympathetic consideration of their employers. Anxiety state resulting from prolonged unemployment and financial insecurity may obscure the picture before a psychiatrist is consulted. It is therefore essential that symptoms due to external stress should be clearly differentiated from those due to the meningococcal infection. The criteria to be used in these cases have already been discussed elsewhere (Pai, 1944).

Independent and extensive inquiries were made to obtain reliable information on patients' personality, previous illness, disposition to neurotic or psychotic illness, intellectual level, and capacity for work before and since meningitis. Letters from relatives, reports of psychiatric social workers, and, in Service patients, personality and efficiency reports by the officers commanding units were available in most cases. On the basis of this information the patients were considered in three groups according to whether their previous personality was (1) good (i.e., well organized and stable), (2) fairly good, or (3) poor (i.e., neurotic or psychopathic).

Symptomatology

When the symptoms were studied in the light of information obtained from various sources it was found that some symptoms appeared to be purely functional in origin and to be precipitated by psychological factors such as domestic and financial stress or unsuitable employment in their units. Among such symptoms were stutter, amblyopia, and hysterical paraplegia (Hurst, 1918) and disorders of gait, and these began after varying intervals of complete freedom from symptoms. As was only to be expected, such symptoms were predominant in patients of the second and third groups, indicating that functional symptoms were more common where disposition to neurosis existed before the meningococcal infection. Some of these patients had actually suffered from somewhat similar symptoms before the onset of cerebrospinal fever, and their present psychiatric disorders more or less conformed to their previous pattern of behaviour to stress.

But functional symptoms were also present in a few patients with previous good personality who had not suffered from any neurotic illness prior to the C.S.F. For instance, three months after recovery from an attack of fever one patient was torpedoed off the west coast of Ireland, and ten days after his return to England the house next to his billet was hit by a bomb. He then developed fainting attacks. Investigation revealed that before his C.S.F. he had been torpedoed twice and had withstood the London "blitz" without showing symptoms of neurosis. In another patient, who complained of pains in the spine and chest, the symptoms had obviously been precipitated by the serious illness and subsequent death of his mother from cancer of the breast with metastasis in the vertebral column. In the case of another patient, who complained of sudden amblyopia about six months after recovery from C.S.F., psychiatric investigation revealed that he was a capable signaller who since his recovery from C.S.F. had developed a fear of oversea service (though prior to the C.S.F. he had twice volunteered to go over-seas), and his hysterical blindness began while home on embarkation leave. The symptoms in these patients were obviously functional, but as they had no history of inherited or personal disposition to neurotic illness previous to the C.S.F. the tendency for neurotic breakdown seems to have been acquired as a result of the infection.

It was, however, difficult to assess whether such symptoms as headaches, blackouts, fits, and temporary loss of memory were predominantly physiogenic or entirely psychogenic in origin. But slowly developing changes in personality, habits, and interests, mild but prolonged depression, intellectual deterioration, and in some patients of hitherto unblemished character moral deterioration as well, involving trouble with the civil authorities, were more suggestive of encephalopathy than of functional disorder. Such changes were striking in patients with previous good personality (though they were also found in other patients), and were confined to those who had had a severe attack of C.S.F. with delirium. These changes more or less began during the initial illness (C.S.F.), and even after extensive inquiries no obvious psychological factors were discovered to account for such symptoms. The evidence for regarding these patients as suffering from an encephalopathy appears, therefore, to be fairly convincing.

Table showing Changes in Personality after C.S.F.

Previous Personality	No.	Details of C.S.F. (D = Delirium)		External Stress	Symptoms Continuous	Psychiatric Disorder	
						Neurosis	Probably Organic
Good	27	Mild	6	4	3	6	—
		Severe, with D	14	3	12	5	9
		Severe, without D	7	2	6	7	—
Fairly good	19	Mild	3	2	1	3	—
		Severe, with D	5	2	5	2	3
		Severe, without D	2	—	—	2	—
Poor	14	Mild	6	5	6	6	—
		Severe, with D	5	3	3	1	4
		Severe, without D	3	1	2	3	—

It would seem that some patients who have apparently recovered from a severe attack of C.S.F. with impairment of cerebral function during the illness may continue to complain of symptoms, some of which appear to be predominantly psychogenic and others most probably physiogenic.

Symptoms of Meningococcal Encephalopathy

Changes in Personality

More or less profound changes in the total personality in children have been mentioned by several writers—chiefly Pette, Pfeiffer, and Redlich, in their handbooks on psychiatry. Moroseness in children previously of a placid and cheerful disposition and in persons with a hereditary or personal history of nervous instability, irritability, and outbursts of passion have been mentioned by Rolleston and Ronaldson (1940).

Various changes in personality were predominant features in most of our patients, especially those (in Group 1) who before the C.S.F. were known to be well-organized and stable persons with plenty of initiative and drive. In general they appeared to have lost the *joie de vivre* and become diffident, and were inclined to spend more time in the comparative security of their homes, moping about and doing practically no useful work. Those who had resumed their work were inefficient, and even the lightest task seemed to be an effort. Employers reported that some of these patients were constantly grumbling, and yet others were frequently asking for concessions from superiors or help from work-mates and relatives.

Intellectual Deterioration

In children, mental enfeeblement, difficulties in learning, and even dementia (Brain, 1940) have been mentioned by several writers. Goeppert points out that in an epidemic in Norway 3.7% of 539 patients showed severe mental deterioration, and after an epidemic in Upper Silesia most of the survivors who could be followed up over a considerable period were reported to have become more irritable and poorer in their scholastic achievements.

The majority of our patients showed some degree of intellectual deterioration. They complained of forgetfulness and of difficulty in calling up old associations and in recalling names, dates, and figures *quickly*. While speaking to their friends they sometimes could not then recall their names, though they could do so after some time. This was probably due to impairment of visual recognition and recall. Forming new associations was an effort, and there was considerable difficulty in planning ahead quickly.

When given a battery of psychological tests (Halstead, 1943) visual memory, as tested with pictures, stories, and reproduction of designs from memory, was faulty, and there was evidence of displacement of major details or confusion. Auditory memory (repeating words, sentences, and stories) seemed fairly good. Retention was short, and there was a substantial drop in the amount recalled after 10 minutes. In some patients there was no improvement even after repeated readings of the same material.

Making mistakes, confusion of details, and bringing in inventions were quite common. Disturbed attention, poverty of associations, and slowness of thinking and planning were also apparent during occupational therapy in the workshops attached to the hospital when the patients had no reason to suspect they were being tested.

Case 1.—A male aged 23 was admitted on April 13, 1943, for investigation—? schizophrenia. He came from a well-to-do family, had a normal childhood, and had been very popular at school, where he was captain of the cricket and football teams. After getting his school certificate with seven credits he became a teacher in a preparatory school, and in 1938 was commissioned in the Forces, where he got on well until an attack of C.S.F. in 1941: During convalescence he could not recognize his father for several weeks, and later complained that his memory was bad. When allowed up he used to get lost. At first he could not remember what he had read and although in this respect he improved after a few weeks he still had difficulty in recalling temporary or unfixed events. Eventually he was invalided out with a 100% pension. After his discharge from the Service he went to a preparatory school as house master and tried to teach mathematics and science, but had memory difficulties: he could remember things he knew long before the illness—e.g., elementary mathematics—but had difficulty in learning new things; he forgot engagements, and others had to help him He tried hard to do new problems in his mathematical work, but owing to loss of memory, headaches, and tiredness, he finally had to give up teaching about the middle of 1942. Next he tried an easier job as progress chaser at an aircraft factory, but was incompetent, and on medical advice was discharged in six weeks. He then remained at home for about eight months, when he used to stay in bed until 11 a.m. and showed no desire to do anything He did not know whether he required work or rest. Finally he left home and went to stay with his uncle (a retired Army officer), who took him to a psychiatrist. The latter raised the question of schizophrenia, and referred him to this hospital. On admission he complained that his memory difficulty had caused him to be incompetent at teaching and factory or any other work. He described his difficulty as a feeling of blankness when he had to deal with a new situation quickly. The harder he tried the greater was the blank, and he felt as if he was in a maze. He also had difficulty in planning ahead quickly, though he could do it *very slowly*. When given a battery of special tests devised by Halstead (1943) his impairment seemed to be mainly intellectual—i.e., in the higher processes His learning ability was poor, his retention was short, and his recal after a second reading of the same material showed no improvement. His vocabulary score was equivalent to an I.Q. of abou

130. He had no financial or other obvious stress to account for his symptoms. Wassermann and electro-encephalogram—N.A.D. During his stay his attitude improved, and he was discharged with advice to do work at a lower intellectual level.

Case 2.—A male aged 21 was admitted on March 16, 1942, for investigation of headaches, loss of memory, depression, and behaviour disorders. There was nothing significant in his family and early history. He was happy and contented, and got on well with his friends and work-mates, who all liked him. "One could not have wished for a better boy." After a severe attack of C.S.F. in 1937 his personality seemed to have undergone a complete change. He had moods quite often, when he was really hateful—he snapped at everybody, the dog seemed to be continuously under his feet, and everything was wrong. As soon as he came in from his work his mother could tell whether he was in a bad mood or not. These moods seemed to last for the rest of the day on which they started. Since his illness he had also complained of severe headaches and intolerance of noise. He could not even bear the clatter of the china when the table was being laid. His memory had been very bad since the C.S.F.; sometimes when he went to work in the morning he would ask his mother to mind something for him during the day, but he would have entirely forgotten this by the evening, and would be asking her what she had done with it. He could even forget where he had put something a few minutes before, and be looking for it in the wrong room. On several occasions he failed to get out of the bus on the way home from work and passed the end of his own road. On one such occasion he found himself in a locality he did not know at all, so that he was forced to ask a policeman where he was. He had also suffered from attacks of amnesia. The first attack occurred about 4 to 5 months after recovery from C.S.F. While on his way home from his factory he suddenly lost his memory and wandered about aimlessly until the next day, when he was recognized by one of his friends, who took him home. About a year later, while sitting with his brother in a picture theatre, he suddenly got up and walked out. After about 15 minutes he "came to" and realized what he was doing. There have also been disturbances of sleep. He used to sleep in a large room with his two brothers, each in a single bed. On one occasion he got up in the night and, going downstairs, opened the front door and went out. The noise made by the banging of the door wakened one of his brothers, who followed him and persuaded him to return to his bed. When his brother pointed out that it was too early and too cold to go out he said it was time to get up. On another occasion he got out of his bed and into that of his brother. The latter did not wish to disturb him and so let him remain, and they both spent the night in one bed.

He had also complained of mild depression, and had been spending more time at home, seldom going out in the evenings. On account of his forgetfulness his work deteriorated and he had frequent changes of jobs. On Feb. 8, 1942, he had another fugue, and was found wandering with loss of memory. A psychiatrist who examined him found his memory defective and his powers of attention, retention, and recall all impaired. During his stay here he was depressed and retarded. After discharge from this hospital on April 9 he stayed at home for a month, then took up a labouring job, but found that the jar of using a pickaxe brought on headaches and in a few days gave this up. After some unemployment he was persuaded to go into a war factory where his two sisters were working. He travelled to and from work with his sisters and worked in the same room, but after about five or six weeks was discharged as inefficient. His subsequent work record continued to be unsatisfactory.

Moral Deterioration

Disorders of conduct similar to those following encephalitis have been reported by Voisin and Paisseau (Kinnier Wilson, 1940) in children who survived the Paris epidemic of C.S.F. n 1910. Mendaciousness and deterioration of character similar o those described in a boy by Kinnier Wilson (1940) were triking features in some of the patients.

Case 3.—A male aged 29 was admitted on Feb. 19, 1943, on account of deterioration of personality. He came of a good family and was popular at school, where he captained the football team. After leaving school he was a cinema operator for 14 years. At 6 he had a severe attack of diphtheria, and since then he appears o have had occasional moody attacks, when he would prefer to be alone. Otherwise he is reported to have been sociable and happy-go-lucky. At the outbreak of war he volunteered for the Army, and after 18 months' service became a L/Sgt. One of his brothers was killed at Dunkirk, another at Coventry during an air raid, and a third in an explosion at a munition factory. In spite of this he eems to have done fairly well until he had an attack of C.S.F. in Oct., 1942, since when his personality has undergone a complete change. He was found guilty of several breaches of discipline, and never returned from leave at the correct time, and in most cases on his return said that he had been suffering from amnesia. His officer stated that it was impossible to place any reliance on him, that it was found necessary to keep him with another N.C.O., and that as he required to be under constant supervision he was therefore not fit to carry out normal duties, which included solitary sentry duty on the gun. His O.C. also remarked that he seemed on the whole to be a man of good type and intelligence, and if cured of his present trouble would probably prove to be a useful and efficient soldier. On account of his steady deterioration he was warned on many occasions and given an opportunity to relinquish his stripes, which he refused to do. However, in Dec., 1942, he broke into a shop and stole about a pound of sweets, which he immediately distributed among his friends. He says he did it on a sudden impulse without realizing what he was doing, as the sentry on duty was not far from the shop. He was subsequently convicted of stealing and sent to a civil prison for 21 days. On the expiry of his sentence he was again A.W.O.L. and was found wandering in the fields. He was then examined by an Army psychiatrist, who referred him to this hospital.

On admission he complained of attacks of confusion, absentmindedness, forgetfulness, headaches, fear of accepting responsibility, lack of control over sudden impulses, loss of libido, and depression. He appeared lacrimose, despondent, and full of apprehension. He complained bitterly that since the illness a change had come over him. Because of this and his complete impotence while home on leave his wife had threatened to leave him. He pointed out that during the periods A.W.O.L. he did not go home, but wandered aimlessly and slept in the fields (this was confirmed by independent report), as he felt a desire to avoid all human beings. During his stay he slightly improved, and was given a posting under the War Office Annexure Scheme, but within about three months he had relapsed and was admitted to another hospital.

Case 4.—A male aged 25, a quiet, cheerful, and well-adjusted professional violin-player, had a severe attack of C.S.F. with delirium in Jan., 1941. During convalescence he began to complain of constant heaviness in the head, with frequent frontal headaches, impairment of memory, disturbances of sleep, undue tiredness, fainting attacks, and persistent depression. His relatives and friends noticed gradual changes in his character and habits. Whereas before the illness he used to spend about five hours daily playing the violin, he now seldom spent more than 10 minutes. Before the illness he used to read two or three books a week, but now he could read short stories only. Acquaintances stated that he had short lapses of memory, and while talking to them could not remember their names. It was reported that he had become mendacious and was inclined to say nasty things in a sarcastic way about his friends, which surprised them, as they had always known him to be a quiet likeable chap who never offended anyone before. He seems also to have done several odd things. For instance, one night he woke up at 2 a.m. and got out of bed to go down for breakfast. On two or three occasions he "collapsed" and was apparently unconscious.

In a slightly unstable individual a severe attack could be followed by deterioration of character and temper, disorders of conduct, and antisocial behaviour.

Case 5.—A male aged 24, admitted on July 28, 1942. Though inclined to be highly strung, he was fairly well adjusted in civil life. Since a severe attack of C.S.F., for which he was three months in hospital, he had been continuously depressed and irritable. He had been unmanageable in his home and also in his unit, where he had been punished for frequent breaches of discipline. He was in trouble also with the civil authorities for disorderly conduct and antisocial behaviour. During his stay here he was dejected, fidgety, and difficult to handle on account of his destructive tendencies. He was untidy, faulty in habits, and inclined to use obscene language, and spat all over the place.

Some of the patients also complained of blackouts, fits, and attacks of confusion, which were at first thought to be hysterical in nature, but which from the evidence of the E.E.G. appeared to be attacks of petit mal or grand mal. Convulsions may have been due to involvement of the cortex, as pointed out by Grinker (1937), or to internal hydrocephalus (Baker, 1934). Jacksonian attacks may be due, as suggested by Dopter, to areas of meningitis which act as irritants to the cortex (Rolleston and Ronaldson, 1940).

Case 6.—A male aged 31 had an attack of C.S.F. in 1940. During convalescence he complained of continuous pressure in the head with frequent headaches on the left side and depression. After three months he tried to resume his previous work but could not, and changed to a lighter job. About nine months later he had a blackout, then twitching and involuntary movements of the right arm and hand, followed by temporary paralysis and recovery. Though some of his symptoms persisted in April, 1941, he enlisted in the Forces (as a volunteer), hoping to shake off some of his depression, but during training had another blackout followed by brief paralysis of the right arm and hand, which caused him to drop the rifle which he was holding. Soon after this he went to sea and seems to have tried his best for several months, but on account of symptoms he reported sick and was returned to shore, where he was given light duties. As he found even these too strenuous, on the advice of the M.O. he was given a light job as a runner, but complained bitterly that he could not do it unless he had a bicycle. When a bicycle was obtained he grumbled that the work was too much for him. For nearly four months he was on sick parade almost every morning. His O.C. stated that at one time he was "well behaved, well disciplined, well turned out, and conscientious," and that he was steadily deteriorating. His relatives also complained about the change that had come over him.

On admission he said that during some of his blackouts he felt dazed, and vague and indistinct figures moved rapidly in front of him ("dreamy state" of Hughlings Jackson). An E.E.G. showed abnormal waves from the left temporal and occipital lobes.

Sexual Anomalies

It has been pointed out that temporary impotence and inhibition of spermatogenesis may occur after administration of sulphonamides and that these disabilities seldom last longer than a few days (Cohen, 1941). Several of our patients complained of loss of sexual desire and impotence lasting several months, and this condition is apparently not the result of chemotherapy, as similar changes were present in some of the patients who had their illness in childhood and who had not been treated with sulphonamides (Pai, 1944).

Case 7.—A male aged 31, happily married, with two children. Following C.S.F. in March, 1941, he lost all heterosexual desire, became impotent with his wife, and gradually began to be bothered with homosexual (passive) fantasies and impulses, with increasing difficulty in self-control. He got worried over his impotence, and the stress of close association with other men resulted in anxiety symptoms regarding fears of giving way to his unhealthy cravings and of the consequences. Finally he sought refuge in alcohol, which made his condition worse and aggravated his depression.

Depression

Nearly every one of our patients complained of mild but prolonged depression without feelings of guilt or self-reproach. They avoided their fellow-beings, lost interest in favourite hobbies, and were disinclined for any form of employment, whether gainful or not. They could not be bothered even to talk to people, and had no patience for any form of recreation or entertainment. The depression was not intense enough to cause fits of crying, and none admitted having ever entertained thoughts of committing suicide—a useful point in distinguishing this condition from neuroses, in which patients often burst out crying and sometimes threaten to commit suicide.

Headache

The great majority of these patients complained of constant heaviness in the head, with frequent attacks of headache. It is difficult to say whether this headache is due to organic changes in the meningeal vessels, to a minor degree of internal hydrocephalus (Baker, 1934), or to the process of disintegration of the personality pattern. Possibly alterations in personality may lower the threshold for pain or cause external stimuli (which ordinarily do not cause pain) to be interpreted as potential threats to the personality, giving rise to the sensation of pain. Hence their frequent remark, "Any noise gives me headache."

Case 8.—A male aged 28, with no previous history of neurotic traits or ill-health, had a severe attack of C.S.F. in April, 1939. It was reported that before this illness he was a very easy man to live with and tried hard to make his wife happy. Since his illness his wife felt she was living with a different man. He was full of complaints about his headaches and used to spend his nights sleeping in a chair in the sitting-room. One day, being unable to bear the pain, he deliberately knocked his head against a wall, and next day had a swelling on his forehead. When questioned by his wife he confessed what he had done.

A few of the patients complained of vague phobias, but in four of these cases specific obsessional trends emerged for the first time since the C.S.F. These features were merely different aspects of the personality changes.

While convalescing from C.S.F. a barber with 11 years' experience developed a phobia for razors, and was obsessed with the idea that if he handled one he might not be responsible for the consequences. Another patient was afraid to sleep in his bed (lest he should not wake up in the morning), and in consequence spent the nights dozing in a chair.

Irritability, aggression, suspicion, and paranoid reactions met with in post-confusional states were either absent or insignificant in our patients, who, generally speaking, appeared to be mildly apathetic. Nevertheless, when faced with tasks which they could not tackle a few showed symptoms of mild anxiety and irritability, due no doubt to frustration.

Discussion

Consciousness is necessary for the full functioning of one's responses to the demands of society. This pattern of behaviour constitutes to a great extent one's personality. When consciousness is disturbed, as in confusional or delirious states, the cognitive, emotional, and volitional functions are impaired, resulting in temporary disintegration of the personality pattern—hence such symptoms as incoherent speech, disturbances of bladder function, and disorders of conduct. When, therefore, changes in the personality pattern persist for some time it would not be unreasonable to assume that some damage remains to those parts of the brain which govern, among other things, the cognitive, emotional, and volitional faculties, or that restoration of these functions has been delayed.

It is becoming increasingly clear that some patients who apparently recover from C.S.F. show a more or less definite syndrome, though individual symptoms may vary in intensity and degree in different patients. These symptoms would appear to progress up to 10 to 14 months and then remain more or less stationary. Whether these changes are the result of damage by the meningococcus or the result of slow vascular changes it is difficult to say. Possibly other factors, such as chemotherapy, biochemical changes, or vitamin deficiencies during the course of the illness, may be at work, either singly or in combination.

Conclusion

In the absence of definite knowledge of the causative factors prophylactic measures cannot be suggested, but certain lines of procedure may be adopted while dealing with patients who during C.S.F. suffer from disturbances of consciousness. As soon as possible (and before the patient leaves the fever hospital) the patient's psychiatric and socio-economic problems should be reviewed, if necessary with the help of a psychiatrist and a psychiatric social worker. By this means a good deal may be done in the way of preventing purely neurotic superstructures. Where evidence of neuro-psychiatric disorder has emerged, although it may be unprofitable to try to label an individual symptom as predominantly psychogenic or predominantly physiogenic, it is clearly essential to decide whether the total picture is suggestive of a functional disorder or of an organic process. In the case of the former, appropriate treatment may restore a patient to his previous functioning level. When there are reasons to suspect an organic process the psychiatrist should assess the patient's efficiency, placing emphasis on his residual capacities rather than on his disabilities and he should be advised and encouraged to work at levels at which he is likely to achieve success. In the early stages this should be done under supervision. Vague advice to "do light work and take plenty of rest" is worse than useless, and has been responsible not only for much unemployment but also for the development of avoidable secondary neurotic reactions.

Summary

Studies were made of 51 patients who complained of neuropsychiatric symptoms after apparent recovery from cerebrospinal fever in adult life.

In the majority of these patients the psychiatric disorder was predominantly psychogenic and the symptoms were similar to those seen in other patients suffering from neurosis.

Of 24 patients who had had a severe illness, with delirium, 16 showed a definite syndrome which was suggestive of an organic process, with perhaps slight functional overlay in a few instances. Case histories have been given illustrating the changes in personality, intellectual or character deterioration, and tendencies to invalidism which were prominent features in these patients.

Persons with no hereditary or personal tendencies to neurotic breakdown may after an attack of C.S.F. acquire a disposition to neurotic illness.

My thanks are due to Dr. W. S. Maclay, the medical superintendent, and his staff for their co-operation.

PSYCHIATRIC CASUALTIES IN A WOMEN'S SERVICE

BY

S. I. BALLARD, L.R.C.P.&S., D.Psych.Ed.
Squadron Leader, R.A.F.

AND

H. G. MILLER, M.D.Durh., M.R.C.P., D.P.M.
Squadron Leader, R.A.F.

ittle has been written of the war neuroses as they affect the omen's Services. From a joint personal experience of nearly ,000 such cases, we believe that some features of interest rise, and that a brief analysis of our material and of the actors leading to breakdown in this minority of the W.A.A.F. opulation may have some importance, not only because of he economic and social issues involved but also in relation o the general theory of the war neuroses.

We are unable to give figures showing the respective incidence f psychiatric disability among men and women in the Service, nd it seems unlikely that such figures will become available uring the war. Many medical officers of mixed units state hat there is an appreciably higher incidence in women. The ccompanying Table shows the diagnoses in two groups of onsecutive psychiatric cases seen.

Diagnosis	Cases among 250 Consecutive Airmen Referred	Cases among 250 Consecutive Airwomen Referred
nxiety states	100	65
ysteria	56	105
sychopathy	70	53
ental defect	8	18
sychosis	12	7
ther psychiatric conditions	4	2

Mental Defect

These cases represent about 7% of the airwomen in our eries invalided on psychiatric grounds, and 44% of the group ere referred because of executive difficulties. We would tress that, at all levels, usefulness in the Service depends more n emotional stability than on intelligence quotients. Two-hirds of these defectives were emotionally unstable, and over hree-quarters had very poor civil employment records. Never-heless some of them do useful work under Service conditions, nd in this they are materially assisted by the existence of ork suited to their intellectual level : they are less likely to e pushed into the technical training which so often leads o rapid breakdown in male defectives.

The few psychotic airwomen seen were not invalided direct, ut were admitted to hospital, and, defectives and psychotics xcepted, the remainder of cases invalided are classified as nxiety states (16%), hysteria (50%), and psychopathic states 34%). It is with these groups, comprising about 90% of our sychiatric invalidings, that this paper is chiefly concerned.

Psychoneurosis

A striking feature is the preponderance of hysterical reactions n the female cases, seen in the table of cases referred and even ore marked in the invalided group.

In general, the clinical features of the psychoneuroses are similar to those found in men, but an important symptomatological difference was noted in that the somatic expressions of emotional disturbance were less common among females, who tended to show an overt emotional upset rather than one masked by physical symptoms. Thus nervous dyspepsia, a common psychosomatic illness in men, is rarely seen in women. When psychosomatic symptoms do occur in the latter they tend to be of a vague type and frequently take the form of headaches, ill-determined emotional faints, "rheumatic pains," backaches, or gynaecological complaints especially related to menstruation. Similarly, major conversion symptoms, fugues, and amnesias are rare among W.A.A.F. personnel suffering from hysteria. It would appear that the socially acknowledged and permitted emotionalism of women allows of a more direct expression of adaptive and emotional difficulties, and that this renders prolonged and inconvenient physical symptoms superfluous. Men, on the other hand, submit to a sterner social and emotional code. They have, therefore, a greater need to preserve their self-esteem by the development of a more complex disguise or escape mechanism.

At the extreme end of the scale a small number of highly unstable young women showed an acute and usually transient breakdown, often hysterical but sometimes schizoid in type. This usually occurred shortly after joining the Service, and represented a complete failure of adaptation. Similar cases were seen in men, who were invariably, however, of low intelligence bordering on the level of high-grade feeblemindedness.

In aetiology domestic factors were important, and were found in a third of all anxiety states in both sexes. A fairly common finding, also in both groups, consisted of feelings of frustration, amounting in some cases to paranoid reactions, which cleared up when an obvious environmental difficulty could be overcome.

Psychopathy and Temperamental Instability

The classification of "psychopathy" covers two distinct groups of cases. First there are the true "constitutional" psychopaths of the predominantly inadequate or predominantly aggressive types. These usually give a psychopathic family history, and have a past record of gross personality difficulties and maladaptation dating from early life. The inadequate and feckless is the commoner type, personified by the shy, over-protected, and often socially "superior" female with interests and activities limited to the immediate family circle. Typically the only or the youngest child of elderly parents, and with a history of minor neurosis, she often stated that she joined the Service on medical advice. Such women are apt to make much of minor ailments and to fail in adapting to communal life, routine work, and the absence of special consideration.

Examples of the aggressive group, who show irresponsibility, unscrupulousness, and rebellious antisocial activity, are not rare. These patients are frequently vivacious, attractive, and intelligent products of parental overspoiling, whose egocentricity is often expressed in conduct disorder or hysterical symptoms in the face of unpalatable regimentation. They are, however, a menace to unit morale and discipline, and, in women at any rate, the Service usefulness of either group is slight.

We have arbitrarily separated from the classical psychopathies a group of temperamentally unstable individuals which is numerically as great, and clinically as important from the Service standpoint, as the psychopaths. While it is obvious that if seen in civil practice these would be classified as psychopathic personalities, their pre-Service social history shows little evidence of maladaptation although their personality structure shows clear indications of psychopathic instability. In civil life, living at their own level, such individuals have been able to compensate their predisposition, and a breakdown with neurosis or conduct disorder of an aggressive or rebellious-type occurs only on exposure to the unusual demands of Service life.

Members of the classical psychopathic groups are usually invalided at an early stage, and it is from the temperamentally unstable group that the "problem cases" of the W.A.A.F. are principally drawn. They are problems from the executive and medical points of view, for while they show gross conduct disorder and ruthless determination in pursuit of their own ends, there is little abnormal to be detected on an ordinary psychiatric examination, and their diagnostic labelling comes to depend upon the history of repeated disciplinary offences, and the failure of repeated disciplinary measures to deter them. In this respect, however, it is to be noted that, while in dealing with men the attainment of some measure of social responsibility can be assisted by disciplinary action, the disciplinary powers in a women's Service are so much less stringent as to be inadequate in many cases, and it is therefore found in practice impossible to push these cases as vigorously and to such effect as can be done with men of a similar type.

Predisposition

In dealing with large numbers of these cases it became obvious that predisposition to neurosis was of considerable importance in aetiology and also in prognosis. By "predisposition" is meant a measurement of the degree of liability of the individual to break down in a neurotic pattern when exposed to stress. In general terms it is assessed by means of a historical survey of personality structure, previous reaction to stress, and hereditary indebtedness. The assessment rests upon the established clinical observation that a subject who has reacted neurotically to past situations is likely to react in similar fashion to present and to future stress. In this connexion 86% of a series of 100 consecutive psychoneurotic and psychopathic members of the W.A.A.F. seen by us showed severe or moderately severe predisposition, and 80% of a similar series of 100 airmen were also graded in this degree of predisposition.

In contrast, control groups of 100 cases of organic neurological disorder in each of the sexes showed only 20% of subjects severely predisposed to neurosis, despite the fact that the control groups included a proportion of cases of epilepsy and migraine, both of which are commonly associated with nervous instability.

In a previous paper (Ballard and Miller, 1944) we have drawn attention to the fact that 48% of airwomen as opposed to 10% of airmen referred with neuropsychiatric complaints were invalided from the Service. It is obvious that the reason for this difference lies not so much in a quantitatively greater amount of predisposition as in qualitative differences in the faults of personality structure, which together constitute predisposition. It is probable, also, that specialists tend to discard members of the W.A.A.F. more readily than they do airmen. We feel, however, that this trend is largely due to an inherent recognition by specialists of greater instability and less adaptability among women. There was a greater tendency among airwomen to lack persistence, which had led to a poor work record in civilian life in 62% of members of the W.A.A.F. as compared with 46% of airmen.

Psychosexual immaturity with poor socialization, sexual maladaptations, over-dependence on parents, intrafamilial ties or friction, and marital failures were found in 73% of W.A.A.F.s but in only 39% of airmen. These trends were important in the production of separation anxieties of all types (home-sickness, family or marital conflicts) and were conducive to the occurrence of neurotic solutions for, and escape mechanisms from, their difficulties. Among the female psychopaths and temperamentally unstable, 28% were "only children," with a record of spoiling and fostered egocentricity: in the equivalent male group 11% were "only children." In the same groups 28% of women as compared with 16% of men were below average intelligence. Traits of emotional instability were found in 73% of the female cases and in 54% of the male series.

There are other important contributory factors in our series: a positive psychiatric family history occurred in 60% of all cases in both sexes, while 41% similarly showed poor health records. These factors, with others analysed, showed general close approximation of incidence in both series. A further important operative factor in the W.A.A.F. lies in the psychobiological significance of service in the armed Forces, implying as it does the subordination of traditional female values and primary biological functions in the compulsory interruption of the reproductive career at its optimum period.

It would therefore appear that adaptive failure is more likely to occur in women on account of the traits of immaturity and emotional and occupational instability. Because of these traits, attempts to drive such women by disciplinary means are likely to result in further neurotic manifestations. We do not, however, believe that discipline should not be used in these cases, and we are of the opinion that if effective disciplinary measures were available in the handling of merely unruly and temperamentally unstable women their conduct disorders would be reduced or better controlled and invaliding would be more closely confined to the psychoneurotics, true psychopaths, psychoses, and the remaining psychiatric casualties. It is the combination of ineffective discipline with qualitative difference of predisposition which accounts for the higher rate of invaliding in women.

Discussion

In relation to the general theory of the war neuroses the incidence in serving women raises some interesting questions. The war of 1914–18 saw the abandonment of the view that the aetiology of these conditions was physical, and replaced it with the psychological view that they arose from conflict between the instincts of self-preservation and self-respect based on the standards of the herd. This conflict had its origin in fear—fear of death or of physical injury. Such a conflict undoubtedly exists under battle conditions, and in these circumstances is perhaps almost universal. Of itself, however, it hardly serves to explain why some break down while others deal satisfactorily with the conflict, nor does it account for the large proportion of war neuroses unrelated to battle stress

While, then, this was at any rate a psychological explanation and a step forward, it has become increasingly evident in this war that such a conflict is by no means the only or even the central factor in most war neuroses in Service personnel The relative infrequency of neurotic breakdown in civilian populations exposed to great physical danger in their familia surroundings, the incidence of typical war neuroses in base troops unexposed to physical stress of any kind, and the occasional occurrence of suicide in such personnel, without the stress of imminent physical danger, all indicate the inadequacy of this hypothesis.

Further investigation has emphasized the importance of predisposition and total personality in determining the nature and degree of neurotic reactions to war conditions, demonstrating the roots of these neuroses rather in earlier faults of personality development than in the immediate situation Scarcely any of the airwomen in our group who broke down with neurotic illness had faced any physical danger; indeed most of them had lived under safer conditions than their sisters at home, yet they broke down with symptoms similar to, if not identical with, those shown by personnel exposed to combatant stress.

Fairbairn (1943) has recently emphasized the emotiona immaturity of the neurotically predisposed individual and his over-dependence on family surroundings, and has drawn attention to the role of home-sickness and separation-anxiety in leading to breakdown in these subjects. Such factors are certainly prominent in a high proportion of the cases under discussion, which illustrate also the closely related influence of unit morale on the incidence of neurotic breakdown. The unit of good morale, whether it be an operational aircraft squadron, a crack regiment, or a ship's company, provides a sense of emotional security and of "belonging" akin to that of the family in its warmth and spirit. Among much of the R.A.F. ground personnel and in the W.A.A.F. this factor is difficult of achievement. A system of individua postings tends to break up the emotional ties which hold together unit morale and, in addition, such events not infrequently provoke emotional upsets in many airwomen prone to the development of strong individual emotional ties of both a heterosexual and a homosexual nature.

Summary

Experience of a large series of cases of neurotic breakdown in a women's Service indicates the paramount importance of predisposition to neurosis. The emotionally immature and over-dependent in particular, stand up badly to separation from home, and anxiety arising on this score is an extremely common factor. The higher incidence of frankly emotional and hysterical disturbances, the less frequent and qualitatively different psychosomatic reactions, and the

problem of psychopathy and conduct disorder in women are noted, and an attempt is made to show the relation of this material to the general problem of the war neuroses.

We wish to thank Air Vice-Marshal C. P. Symonds, C.B., and Air Commodore R. D. Gillespie for encouragement and criticism in the preparation of this paper.

LUDWIG'S ANGINA

BY

JOHN FARR, F.R.C.S.Ed.
Major, R.A.M.C.

AND

E. D. STANHOPE, L.D.S.R.C.S.
Major, A.D. Corps

Ludwig's angina, if not promptly recognized as such, is often fatal. This symptom-complex of a floating tongue with submandibular cellulitis is not uncommon among East African native troops, and during the last 30 months we have had to treat 20 such cases. It is the purpose of this paper to direct attention once again to the cardinal signs which herald the onset of the syndrome and to outline a system of management which has proved satisfactory and, in our experience, has appreciably reduced the mortality.

The higher incidence among native troops may be due to several factors. Kekwick and Wright (1945) have recently demonstrated that low-grade vitamin C deficiency is prevalent, and it is possible that this leads to a decreased resistance to oral sepsis. The African also has a well-recognized liability to coccal infections, and submandibular cellulitis may be just another manifestation of this tendency. Further, the native shows a hesitancy in seeking dental treatment until he suffers from marked disability, and in some cases this neglect has nitiated the condition.

Where the focus of infection in Ludwig's angina is dental the third lower molar is most commonly the tooth involved, for he following reasons. The inner alveolar plate is thinner han the outer, thus facilitating the spread of infection deep o the cervical fascia and myelohyoid muscles. Again, despite the fact that the African is more prognathous than the European, here is sometimes insufficient room for the complete eruption of the third lower molar. This partially erupted tooth is consequently more prone to pericoronal infection. Alternatively, he infection may be periapical in origin, arising from any of he lower teeth.

An intermediate stage in the pathology is an acute alveolar abscess in the case of periapical infection or a pericoronal abscess in the case of a partially erupted third lower molar. t is imperative to recognize the differential diagnosis between an uncomplicated alveolar or pericoronal abscess and one in which the sepsis has spread into the deep structures of the loor of the mouth, for in the latter stage intraoral drainage by extraction of a tooth or removal of a gum-flap will not provide adequate drainage once the pus has tracked forward n the slanting trough of the myelohyoids, and prompt external drainage is essential. For this reason, where such a spread s a possibility, it is important that the patient should be seen by both a surgeon and a dental surgeon, and that subsequent reatment should be carried out in the closest collaboration.

The cardinal signs (Fig. 1) are:

1. *A Floating Tongue.*—An inflammatory process with or without ormation of pus in the floor of the mouth, firmly embraced by he myelohyoids and deep cervical fascia, causes the tongue to be levated, and in severe cases extruded. Intraoral oedema is pronounced, and in some cases reaches up to the necks of the teeth. Dyspnoea and dysphagia may result from oedema or from pressure on the trachea and oesophagus.

2. *Submandibular Cellulitis.*—This is a diffuse and tender swelling beneath the jaw which may cross the midline of the neck. It must be emphasized that it is extremely dangerous to withhold treatment while awaiting fluctuation, for the patient may succumb to toxaemia or respiratory obstruction before pus is formed, and it is essential that pressure on the deep structures be relieved by sectioning the deep cervical fascia and one or both myelohyoid muscles. Others have reiterated that when the tongue is elevated and there are signs of a submandibular cellulitis the patient is suffering from Ludwig's angina. The diagnosis of the lesion is the indication for operative treatment. Delay is dangerous, and in our opinion surgical intervention is urgent when these two signs are manifest.

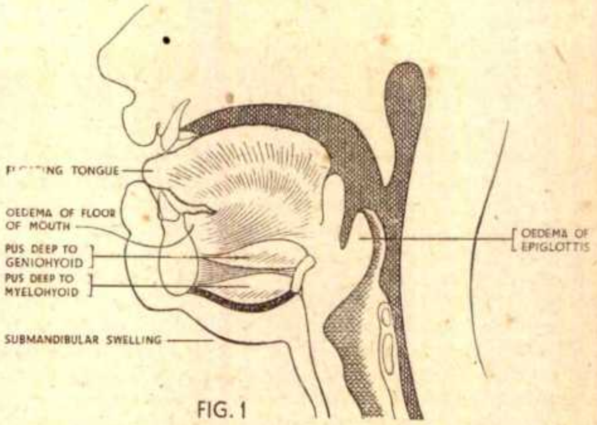

FIG. 1

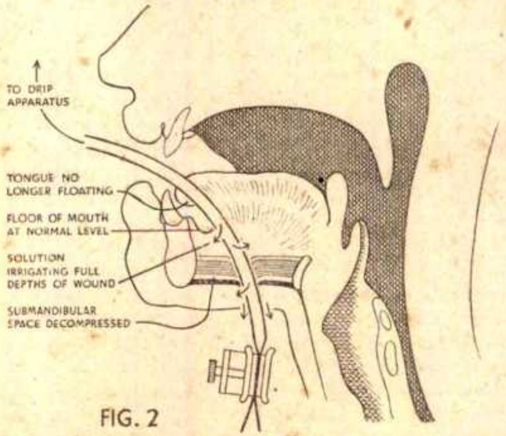
Surgical Preparation

It is of paramount importance that a tracheotomy set should be available in the theatre, and should accompany the patient on his return to the ward. It must remain there for 24 hours, or longer if indicated. This simple precaution is not superfluous, and must never be omitted from the surgical routine. The choice of anaesthesia is determined by the facilities available. We have found local analgesia to be unsatisfactory because of its inability to allow adequate dissection. Ethyl chloride is hazardous in the extreme because of the tendency to spasm of the laryngeal muscles. Where full hospital facilities are at hand the safest method of anaesthesia is by endotracheal nitrous oxide and oxygen, to which a small quantity of ether may be added. Where such facilities are not at hand we have found light chloroform analgesia to be the safest method, preceded by adequate premedication, but, as in any form of anaesthesia, the most important factor remains the skill and experience of the anaesthetist.

Operation

A curved incision is made about one inch below the mandible, extending from a point below the third molar to the midline, or across the midline if indicated. This is deepened to the level of the myelohyoid, which is sectioned. Frequently pus has spilled over the posterior border of this muscle and is found superficial to it, but provided the origin of the inflammatory process is not in the submental glands, section of the muscle is indicated. A drain is introduced, but instead of merely draining the space it is passed on through the floor of the mouth, emerging between the lingual border of the mandible and the tongue (Fry *et al.*, 1942). The part of the tube that is lying in the submandibular structures is fenestrated (Fig. 2).



TO DRIP APPARATUS
TONGUE NO LONGER FLOATING
FLOOR OF MOUTH AT NORMAL LEVEL
SOLUTION IRRIGATING FULL DEPTHS OF WOUND
SUBMANDIBULAR SPACE DECOMPRESSED

FIG. 2

The proximal end of the tube is brought out through the mouth and fixed with adhesive plaster to the side of the cheek. The distal end is anchored to the skin at the site of the incision. Vaseline packing is gently tucked into the incision, and the tube is occluded by a clamp at its distal end. If the condition has had a dental origin the extraction of the tooth involved completes the operation.

Post-operative Care

Chemotherapy in the form of sulphonamide drugs is used as a routine auxiliary treatment. Gas-forming organisms often predominate in the infection, and in at least two of our cases gas under tension has escaped on incising the deep cervical fascia. We have therefore used hydrogen peroxide 1/10 as an irrigant. It seems likely that zinc peroxide suspension would be more efficacious, but its availability is limited. During the patient's waking hours there is a continuous slow drip of irrigating solution introduced through the proximal end of the tube. This escapes from the openings in the tube and allows the region to be gently irrigated throughout its various layers (Shepherd, 1940). The fluid coming out of the incision around the sides of the tube presents some difficulties, as it tends to drip down the side of the neck, but with diligent and zealous nursing care it may be collected in a kidney dish hung on the patient's neck, or a close-fitting jaconet collar.

When continuous irrigation has not been convenient we have compromised with 100-c.cm. irrigations every four hours, after which the clamp is removed and the tube functions as an ordinary through-and-through drain. After 48 hours the general and local improvement is sufficient to consider shortening the tube. It is cut away flush with the buccal mucosa and shortened about half an inch. If further irrigations are indicated at this stage, they are most easily carried out by introducing a small catheter beside the drainage-tube and syringing hydrogen peroxide through it. The drainage-tube is removed on the fourth to sixth post-operative day, and a vaseline dressing, changed when necessary, completes the post-operative dressings.

Although all these incisions have healed by slow granulation and subsequent epithelization, a linear scar results, and no cases have required excision for cosmetic reasons.

Summary

Possible reasons are outlined for the relatively high incidence of Ludwig's angina among East African native troops.

The diagnostic signs that make surgical intervention imperative are stated.

A system of management is described effecting free drainage and submandibular decompression followed by a drip irrigation.

We wish to record our thanks to Brig. R. P. Cormack, O.B.E., D.D.M.S., East Africa Command, and Col. D. Bell, O.B.E., E.A.A.M.C., for permission to publish this paper; and to acknowledge the co-operation of S/Sgt. F. Finch, R.A.M.C., for the production of the accompanying diagrams.

INGUINAL HERNIA IN THE MERCHANT NAVY

AN ANALYSIS OF 200 CONSECUTIVE CASES

BY

PERCIVAL P. COLE, F.R.C.S.

E.M.S. and Senior Surgeon, Dreadnought Hospital

The incidence and cure of hernia have attracted renewed and critical attention from the point of view particularly of the associated disability in men of the fighting Forces. Detailed observation and docketed conclusions have been made possible by the concentration of large numbers of men under an organized and centralized medical service. Inguinal hernia has been made the subject of a critical review by Brig. Harold Edwards (1943), who deals with it comprehensively but also with special reference to Army statistics and military considerations. In the Army, selection of cases for operation is determined by the answer to the question whether operation will make the man a more efficient soldier. In the Merchant Navy—not ranked as one of the fighting Services—the question is the mor vital one of going to sea or not.

Classification

To emphasize particularly the age at operation, the larg number of cases requiring supplementary repair, the larges portion of direct hernias, and the early age at which direc hernia occurs, the 200 cases under review have been classifie numerically into the following groups:

Type of Hernia.—Oblique, 97; direct, 103.

Age at Operation.—53 cases were over 45, 38 were over 50, 19 wer over 55, and 9 were over 60.

Recurrent hernias dealt with in this series numbered 22. Of these 18 were direct and 4 were oblique. Four of these recurrence followed a previous filigree operation, and occurred thereafter: 1 a 10 months, 1 at 6 years, 1 at 12 years, 1 at 25 years.

Primary direct hernia occurring at the age of 40 and under, 2 cases. Earliest age at which direct hernia was found, 23 years.

Number of cases dealt with by filigree repair, 130. The firs operation was performed on Feb. 19, 1941, and the last on June 26 1944.

For the purpose of comparison with procedure in the recognized fighting Services a brief analysis will be based upon tha embodied in an Army Medical Department Bulletin on Inguina Hernia, issued by the War Office in Feb., 1943. Therei it is stated that over 12% of inguinal hernias recur after operation, and this recurrence rate is regarded as representative o British surgery as a whole; the factors concerned are considered to be: (1) surgical skill and experience of the operator (2) selection of cases for operation; (3) operative detail (4) post-operative management.

Analysis of Cases

1. In connexion with this factor all the cases have bee operated upon either by me or under my direct supervision.

2. *Selection of Cases for Operation.*—Under this heading th Memorandum excludes the following categories as being unsui able: (*a*) small bulges in men of inferior abdominal musculature; (*b*) large scrotal hernias in pot-bellied subjects of poo physique; (*c*) large recurrent hernias in similar subjects (*d*) large hernias in men of low category because of othe disorders. Among the 200 cases on which this analysis is base will be found instances included in the first three categorie and, in fact, discrimination on these lines has not been exei cised, for it is a cardinal principle that no case is rejected o account of the local condition. With regard to category I am in agreement with this reason for rejection, but actuall no such case has been met with. As I have previously state (Cole, 1941), the operability rate in my hands, taking all case into consideration, is 90% at a modest estimate.

3. *Operative Detail.*—Under this heading it is stated that 75 of recurrences after operation for indirect hernia were indirec Authorities such as Page (1934), Block (1933), Ogilvie (1937 and Gallie and Le Mesurier (1924) have agreed that by far th greatest number of so-called recurrences after operation fo oblique hernia are direct in form. It is clear that in this mas reproduction of the original condition (75%) responsibility mu be attributed to factors either non-operative or operative to minimal extent in the collected series of the quoted authoritie Prior to the series under survey, and over a period of 20 year recurrent hernias numbering approximately 400 have bee observed, and the mode of recurrence has been so often dire that this predominance has never been questioned. The sma number of recurrences in the present series bears this out, fo it will be observed that of the 22 recurrences included 18 we direct and only 4 oblique. Recurrences, the Memorandu states, are commonest after the Bassini operation or one its modifications. With this my own practice records agreement, for I have not performed a Bassini operation for man years. I further agree with the recommendation that "n type of operation which interferes with the normal muscul apparatus of the inguinal canal should be practised for uncomplicated indirect hernia in the young soldier"; and in th connexion it is the age of the patient that counts and not th nature of his employment.

Apart from this simple type of hernia occurring in the your man, some supplementary method must be employed to repla or reinforce the failed inguinal canal. This applies to the ong-standing oblique hernia, for the control of which a truss has frequently been employed for varying periods up to several years, and to all cases of direct hernia.

The supplementary measures recommended for use in the Army involve the employment of fascia in various ways. The supplementary procedure adopted in this series of cases is that of silver filigrees. No case has been subjected to this procedure unless the indications have been perfectly clear. In other words, 130 of the 200 cases have been of such a nature that cure could not have been expected without resort to this or some other method of supplementary repair.

Textbooks are in substantial agreement that the treatment of direct hernia is modified by the fact that this type of lesion usually occurs in elderly men. I believe that direct hernia at earlier ages occurs more frequently in men of the Merchant Navy than in other walks of life. Whether this be so or not, t is significant that of the 200 cases operated upon 103 have belonged to this category, that 27 of these have come to operation at or under the age of 40, and that direct hernia has been found at the early age of 23. In connexion with the question of age, it is noteworthy that 53 hernias in this consecutive series occurred in men of over 45. I suggest that in none of he three recognized fighting Services would men of such an age apply or be referred for operation with the sole objective of resuming or maintaining their active and hazardous participation in the prosecution of the war.

Sepsis.—The Memorandum previously cited refers to "sepsis n hernia wounds." "Sepsis," it states, "is relatively common." n this consecutive series sepsis has been entirely absent except or an occasional transient superficial affection of the skin margins. I attribute this to the fact that the so-called non-ouch technique has been the ideal aimed at. Skin towels are nvariably used, handling of the tissues in the wound is reduced o a minimum and in most cases rigidly excluded. This technique has been facilitated by the routine use of the central-yed or double-pointed needle (Cole).

4. *Post-operative Management of Filigree Cases.*—Following filigree operation patients are confined to bed for three weeks. Normal activities are gradually resumed until full work is underaken at the end of four months. No systematic post-operative xercises have been prescribed.

End-results

Return to Duty and Morbidity.—It is significant that all ases operated upon have been returned to the reserve pool, nd, so far as I know, have resumed their duty at sea. Moridity even has been negligible. In only one case was return o duty delayed beyond the normal period. This was due to he occurrence of femoral thrombosis on the opposite side some weeks after operation.

Recurrences.—Of the 22 recurrences in this series four ccurred, as noted, after a primary filigree operation. Repair n each case was by additional filigree, with uniform success nd return to work.

Filigree Recurrences in the Merchant Navy.—In the 10-year eriod 1930–9, 202 recurrences were met with out of a total f 2,015 operations, and of these recurrences only 12 followed filigree operation. The number of filigree operations performed in this period was 448. The filigree operation has been rgely confined to the Dreadnought Hospital for many years, nd it is not unreasonable to suppose that cases of recurrence ollowing its performance would return, be returned, or be ported. It might be suggested that the 12 recurrences met ith in 1930–9 were partly applicable to a preceding period hen few such operations were undertaken. This objection answered by the fact that in the preceding five years—1925–9 -287 cases were dealt with by this method. In view of the igh operability rate and of the fact that the operation is served for cases that demand some supplementary method of pair, a high group incidence of recurrence might well be xpected. The figures cited clearly suggest that the recurrence te attaching to this operation is remarkably low.

The method of filigree repair has been accorded a recognized ace in current surgical practice in the pages of the most cent—third—edition of *Modern Operative Surgery*, and the editor, Prof. Grey Turner, in a short historical survey states that "the lapse of time is showing that this plan has attained more success than has been acknowledged."

Details of the technique will be found in an article contributed by me to the *British Journal of Surgery* (Cole, 1941).

Illustrative Cases

1. Second Officer, aged 27. Six months' history. Right inguinal hernia. Operation March, 1942. *Small direct bulge.* Repaired by two filigrees.

2. Navigating Officer, aged 27. Right inguinal hernia, *gradually coming on for six years,* with more rapid increase lately. Operation Nov. 16, 1942. Conjoined tendon very poorly represented. Hernia presented as *diffuse direct bulge.* Deep epigastrics tied. Repaired by two filigrees.

3. A big stout man, aged 60. Irreducible left inguinal hernia. Operation June 16, 1941. Sliding hernia of the sigmoid. Repaired by two filigrees. Thereafter hernia developed on right side (a tribute, surely, to the efficacy of the left-sided repair). Operation June 26, 1942. Direct bulge. Repaired by two filigrees.

4. Master, aged 52. Weight 12 st. 8 lb. Saddlebag type of sac. *Diffuse direct bulge* of the posterior wall, continued behind epigastric vessels into the cord. Epigastric vessels tied. Repaired by two filigrees.

5. Quartermaster, aged 54. Left inguinal hernia of 10 years' duration; right inguinal hernia of 9 years' duration. Wearing truss for 9 years. Operation Aug. 31, 1942: *Direct* left inguinal hernia repaired by two filigrees. Sept. 14, 1942: *Direct* right inguinal hernia repaired by two filigrees.

6. Steward, aged 51. Six months' history. Chronic cough. Right inguinal hernia. Operation June, 1942. *Direct bulge.* Lipoma of cord excised. Repaired by two filigrees.

7. Tug driver on the Thames by night and day, aged 59. A big stout man of 14 st. Right inguinal hernia for 20 years, at first reducible, but lately becoming irreducible. Operation only alternative to giving up his employment. Operation Nov. 27, 1941. Large oblique sac to which omentum was adherent and of which 4½ lb. was ligatured and removed. Repaired by two filigrees. Has gained over 2 st.—16 st. 8 lb.—and has forgotten about his hernia. In a letter received Aug. 25, 1944, he states: "I have never felt better. I am still at work, and have not lost a day's work since you discharged me. I have felt no effects of my hernia." This has been confirmed since by personal contact.

Medical Memoranda

A Fatal Case of Tetanus despite Toxoid

Active immunization against tetanus was introduced into the Army in 1939, Boyd (1938) doing the preliminary work. The present practice is to give a primary inoculation of two 1-c.cm. doses of tetanus toxoid spaced six weeks apart, and 1 c.cm. thereafter yearly as a recall dose. All available figures (Bensted, 1940; Smith, 1941) confirm that good protection is given thereby, but individual exceptions may occur as in the comparable immunization against diphtheria. Knowledge of the duration of protection rests at present, however, almost wholely on laboratory studies. A number of non-fatal cases of tetanus despite toxoid have been described, but reported fatal cases are rare (Boyd and Maclennan, 1942; McGill, 1943; Norman, 1943).

CASE REPORT

An Anglo-Indian aged 40 came under treatment on Feb. 7, 1944. for prolapsed, inflamed, and ulcerated piles. These were ligatured and excised ten days later under stovaine analgesia. On Feb. 26, seven days after the operation, uncontrollable jerking of the legs began, and on Feb. 29 spasms of the abdominal muscles and fever followed. Next day the neck and jaw were stiff, and infrequent short opisthotonic spasms began. On March 2 fully developed tetanus was present, with severe spasms, each lasting a second or two, and recurring every half-minute or less.

Specific treatment consisted of 1 c.cm. of tetanus toxoid, and of 1,010,000 i.u. of serum spread over the next four days. Avertin and intravenous nembutal were used symptomatically. He died on the eighth day of the disease (March 5), and, apart from bronchopneumonia, the necropsy revealed nothing. The operation wounds were quite healed. His pay-book showed that he had received two tetanus toxoid inoculations, one each on Oct. 18 and Dec. 18, 1941.

COMMENT

Clearly no massive amount of antitoxin was produced here, and the inference is that the immunity resulting from his prophylactic inoculations was slight or absent. Inoculations with tetanus toxoid cause antitoxin to appear in the circulation, but, more important, they also sensitize the reticulo-endothelial system, so that subsequent toxoid or toxin results in a rapid rise in circulating antitoxin. Data regarding the minimum protective level of antitoxin are based upon animal experiments, figures ranging from 0.001 to 0.1 i.u. of antitoxin per c.cm. of serum being given. A primary two-dose inoculation of toxoid rarely produces more than 0.1 i.u. of antitoxin per c.cm., whereas a recall dose later on causes a marked rise (2–50 i.u.). This level falls steadily thereafter, but is readily raised again by further recall doses (Wolters and Dehmel, 1943).

Hence it is unlikely that a high level of circulating antitoxin was ever established in this case, and in the ensuing 26 months it must have fallen very low. There is therefore no need to postulate any original failure to form antitoxin, or any original absence or subsequent loss of reticulo-endothelial sensitivity, in order to explain the fatal outcome.

Although not proved bacteriologically, the clinical course suggests that the anal region was the source of the infection, and that the tetanus bacilli were introduced at the time of the operation. Such a hypothesis puts the incubation at seven days, which accords with his rapid death. Possibly it would have been better to delay operating; the current practice (Naunton Morgan, personal communication) is that with inflammation, thrombosis, or ulceration of internal haemorrhoids, operation is not undertaken for about six weeks.

A recall dose of toxoid a week before operation might well have protected this patient, and it is suggested that this would be a reasonable precaution in such cases.

My thanks are due to Brig. W. Foot, *M.C.*, for permission to report this case.

The Demonstration of Schüffner's Dots in Benign Tertian Malaria

Although the demonstration of Schüffner's dots is not necessary for the recognition of *Plasmodium vivax* infections, the inexperienced malariologist will be more satisfied if these are seen. The method described has been in use for some months, and has so far never failed to demonstrate the dots; it depends entirely on the control of the *p*H of the staining solution at *p*H 7.0, for an identical procedure carried out at *p*H 6.4—that usually advised for blood films—fails entirely.

The stock buffer of *p*H 7.0 is M/2 phosphate, containing 2 molar proportions of the disodium to one of the monopotassium salt. 29.85 g. of $Na_2HPO_4.12H_2O$ (or 19.85 g. of anhydrous salt) and 5.67 g. of KH_2PO_4 are dissolved in water and diluted to 250 c.cm.; this solution is nearly saturated, and keeps indefinitely at room temperature in a glass-stoppered bottle containing a few drops of chloroform. For use, 5–15 drops of stock buffer are placed in a test-tube and about 15 c.cm. distilled water is added. Giemsa solution is prepared by adding 1 drop of Giemsa stain (Gurr's R 66) to each c.cm. of dilute buffer, and is used within 30 minutes of dilution.

A thin blood film is allowed to dry, fixed in Leishman's stain for 15–60 seconds, and the stain diluted with about two volumes of dilute buffer. After 10–15 minutes the stain is poured off, any precipitate removed by rinsing in Giemsa solution, and Giemsa solution left on for 20–30 minutes; the film is rinsed in buffer solution, blotted, and dried. Schüffner's dots are so prominent that they are more easily seen than the malaria parasite.

The quantities of each solution and the times of staining are not critical, but the times given are minima, for it is very difficult to overstain. Similar results can be obtained by several hours' staining in Giemsa at *p*H 7.0, but not with Leishman's stain alone. Several batches of Leishman's stain provided by the L.C.C. Pathological Service have proved entirely satisfactory.

Reviews

THE ELECTROCARDIOGRAM

The Electrocardiogram. Its Interpretation and Clinical Application. By Louis H. Sigler, M.D., F.A.C.P. (Pp. 403; illustrated. $7.50 or 42s.) New York: Grune and Stratton; London: William Heinemann.

The Electrocardiogram by L. H. Sigler is an interesting book This rather technical subject is made more easily understoo because it is presented in a sensible manner. There is a full reference as possible to the physiological aspect of th abnormality under discussion, so that as early as possibl a link is established with the first foundations of clinica knowledge. The whole subject has now been in existence lon enough for it to be possible to give a short historical accoun of the growth of knowledge and formation of ideas on th various topics. This helps to keep matters in correct perspective. The pathological changes in the myocardiu which underlie abnormal curves are well described wher this is possible. There is also a full clinical descriptio of each subject, so that the book is far from bein merely an academic discussion, but keeps the practica application in view. For anyone unacquainted with electrocardiography, study of the first three chapters will provide sound introduction, for the basic principles are clearly described The complicated subject of the electrical axis is well set out Sections are devoted to changes in the curve due to artefacts which are traps for the inexperienced. The effects of bod build and drugs and chemicals are included. The arrhythmia are dealt with in the usual classification. An excellent accoun is given of the various types of bundle branch block an of other miscellaneous varieties of abnormality in the QRS There is a chapter on the abnormalities of the coronar circulation, and two others on acute and chronic coronar insufficiency. These are all very good. Trauma of the hear receives full discussion; also myocarditis, in which is include pericarditis. An informative chapter on the various importan precordial leads concludes the book.

The illustrations are very complete, and nothing seems t be omitted. They are fully documented from the clinica aspect. Unfortunately they appear as direct positive print and are sometimes rather faint and indistinct. It is particularl satisfactory that progressive changes in curves are well shown A full and up-to-date list of references ends each chapte The exposition is for the most part clear. The author doe not hesitate to put forward his own theories, but alway finds place for a fair discussion of debatable points. Her and there are some slips, among which the "tetralgia" o Fallot needs correction. This useful book can be recommende to anyone starting to learn the subject, and to the expert fo reference.

OLD AGE IN HEALTH AND DISEASE

Old Age. Some Practical Points in Geriatrics. By Trevor H. Howell, M.R.C.P.Ed. (Pp. 50. 4s. 6d.) London: H. K. Lewis and Co. 1944.

The somewhat sudden realization that we are an agein community has caused more interest to be taken in the scienc and art of geriatrics. The special value of Capt. T. H. Howell contribution to the subject is that it is based on his own exper ence as deputy physician and surgeon at the Royal Hospita Chelsea, which gave him ample opportunity of studying o age in health and disease. Degeneration, chronic infection and ischaemia are the predominating troubles of the age Attendants upon them tend to coddle their victims and t regard them as lacking in common sense: "they forget th old age is not always synonymous with delicate health an stupidity. . . . Anything tending to self-pity must be avoide . . . it makes a poor tonic for old folk." At the Roy Hospital, Chelsea, it is noteworthy that the fittest veterans a the men who keep their own plot of garden and who enj a game of bowls. (It has been well said that the Psalmist declaration concerning threescore years and ten has bee responsible for much premature senility; for ageing is oft a matter of the mind.) The author's observations do n support the statement often made that temperature either ris or remains at the normal level among the aged; he found a tendency for it to fall after 70. On the other hand, a systolic blood pressure above 160 mm. is common, and among the oldest patients the fittest were those with a high pressure, which is needed to counteract the arteriosclerosis that becomes more pronounced with age. A high blood pressure, marked thickening of the arteries, cyanosis, cardiac murmurs, and enlargement of the heart Capt. Howell found to be compatible with a relatively normal range of senile mental or physical activity. But a vague or muddled state of mind in a patient previously lucid, if accompanied by a fall of blood pressure, is a sign of progressive cerebral ischaemia with an invariably fatal prognosis. In general, diminution of tone is the earliest sign of a turn for the worse in an elderly patient, affecting first the striped and then the plain musculature.

A practical and helpful little book.

THE TUBERCULOUS PATIENT AT HOME

The Care of Tuberculosis in the Home. By James Maxwell, M.D., F.R.C.P (Pp. 105. 7s. 6d.) London: Hodder and Stoughton.

From a book by this distinguished physician much is expected, and in a period when the concept of sanatorium treatment for all tuberculous patients has been modified by a shortage of available beds, the need for sound home treatment is indisputable. Not only the patient but his anxious wife, apprehensive friends, and alarmed relatives need all the information we can give. Often it is easier to bring to the patient understanding of the best policy towards the disease through others than by direct advice. The teaching in this book is sound, and the author knows tuberculosis so well that it is a pity he does not reveal the same intimacy to the reader. The clinical lecture is worth hearing, but the teacher never descends from the platform, and one misses in his chapters an appreciation of certain subtleties that occur between the patient and his disease in the course of tuberculosis. Nevertheless the author's advice is unexceptionable.

The account given in the last chapter on antituberculosis administration is too vague to enable the ordinary reader to form a clear conception of what the community has done to combat tuberculosis in the last thirty years. The good material, authority, and sound intentions of this book are marred by heir inadequate presentation.

SELECTION OF PERSONNEL

Large Scale Rorschach Techniques. A Manual for the Group Rorschach and Multiple Choice Test. By M. R. Harrower-Erickson, Ph.D., and M. E. Steiner, M.A. (Pp. 419; illustrated. $8.50 or 47s.) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox.

his book records the application of the Rorschach tests to roups. It can be done by displaying the ten standard ink lots on lantern slides, each member of the group writing his esponse, or by providing each member with a booklet with lanks for responses. Records were made of spontaneous nswers by several groups, but their interpretation was found o need the services of skilled Rorschach specialists, and this ook up much time. To save this a multiple-choice ethod was used—i.e., ten possible interpretations f a blot were given and the subject asked to dicate the one which most appealed to him, or to ive the order of all in order of preference. It is ought that, at least in skilled hands, this method ay be useful in determining potential psychiatric asualties in any group. The method may also be useful in ifferential diagnosis of psychiatric cases. This book will be f interest to all those concerned with selection of personnel, subject which is likely to become increasingly important in e future.

Notes on Books

actical Wound Treatment, by Mr. EDWARD AKESTER, is a first-aid ook illustrating the use of the "pad and bandage" as issued to all rvices. Gale and Polden Ltd., of Aldershot, publish it at 1s. 6d. y post 1s. 8d.). The presentation is concise, clear, and convincing, d the simple line drawings are excellent. Dr. J. L. Barford ntributes a short foreword commending the work and testifying om personal experience to Mr. Akester's skill in the teaching of st aid at the Surrey County Council Rescue School, Leatherhead.

One or two small criticisms may be made. The author does not seem to mention anywhere the elementary and self-evident method for the temporary control of arterial haemorrhage—namely, actual digital pressure by thumb or finger upon the bleeding spot. It is difficult to understand why the face is not delineated in Fig. 21. Although the pamphlet is a little too large for the male coat pocket it is one that could well be carried by every first-aid worker.

Mr. WILFRED SHAW's *Textbook of Gynaecology* (J. and A. Churchill; 24s.) is now published in its fourth edition; both the second and third were reprinted. The text has been carefully revised, with additions on endocrinology and chemotherapy, together with the addition of 16 new diagrams. This work will continue to be one of the most popular textbooks available on the subject.

Miss A. E. GLENNIE and Miss J. L. H. KEUNEMAN continue their useful task in compiling the *Index to the Literature of Food Investigation* under the auspices of the Department of Scientific and Industrial Research. Vol. 15, No. 3, December, 1943, including items 965 to 1445, has now been published by H.M. Stationery Office at 4s. 6d., and is arranged on the usual lines.

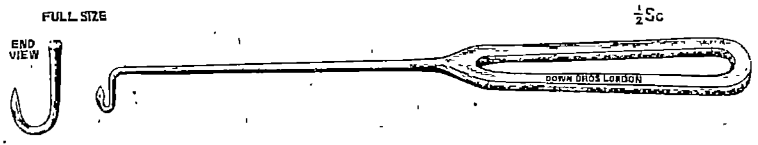
Dogs Against Darkness, by DICKSON HARTWELL, is published at 16s. by Rich and Cowan. Though from our early days most of us have seen blind beggars with their dogs it is only in the present century that canine intelligence has been seriously studied, and the modern guide dog is the result. Dogs are being used by the Police and Army to an increasing extent and as conductors to the blind. The end of this war will see several thousand sightless young men ready to take up a living, and this book is a timely and valuable help towards aiding them to regain their independence of movement; but it is to America, thanks to the passionate devotion of Mrs. Dorothy Eustis, that we owe the scientific development of these special dogs. In England there is an active "Guide Dogs for the Blind Association" established at Leamington Spa. As the book shows, the initial stages of training require unlimited patience. The education of a dog covers a period of three months—obedience exercises, guide work, and the all-important "educated obedience"—e.g., refusing to lead its owner against obstacles or stopping him from crossing a street unless he can safely do so. The illustrations depict blind men striding along confidently through heavy pedestrian traffic, relying on their intelligent and faithful canine companion. Sir Ian Fraser in a foreword urges the importance of this Guide Dog Movement—a great boon to the blind.

Preparations and Appliances

A NEEDLE FOR FEMORAL HERNIOTOMY

Mr. J. COSBIE ROSS, F.R.C.S., Liverpool, writes:

The results of Lotheissen's method of repairing femoral hernia are so satisfactory that the "lower" operation has been gradually superseded. For the same reason fascial repair is generally unnecessary. There are, however, technical difficulties in performing Lotheissen's operation, usually due to two factors: 1. Obesity of the abdominal wall, making it necessary to place the suture at the bottom of a deep, narrow wound. 2. A massive deposit of extraperitoneal fat which tends to foul the needle point.



There is no room to manœuvre the needle in the narrow cleft-like wound when attempting to insert the suture in Cooper's ligament. Even a small-size half-circle needle is too broad for manipulation in such a case. Some years ago I designed a needle (see Fig.) which overcomes this difficulty. The usual half-circle needle is converted to a narrow half-oval which can be handled in a most confined space. When the suture has been thrust through Cooper's ligament one end is drawn up to the surface by means of a blunt hook.

I have used the needle in over a hundred operations and have been satisfied with both the ease and speed with which the repair can be completed. Incidentally, it is, I think, an advantage to include the lower border of the conjoint tendon and the fascia transversalis in the suture apposing Cooper's and Poupart's ligaments.

The needle was made for me by Messrs. Down Bros., who have ensured that the eye is large enough to take a substantial suture.

SHOULD MEASLES BE TREATED IN HOSPITAL?

In the past two decades the policy of increasing the available beds for the care of measles in isolation hospitals has been adopted by many local authorities on the grounds that the serious complications of the disease, particularly bronchopneumonia, may best be prevented and treated in hospital and that fewer beds are nowadays needed for the isolation of scarlet fever because of the continued mildness of the infection. During the biennial measles epidemics in London before the present war many thousands of measles patients were admitted each season to the L.C.C. fever hospitals, and a progressive reduction in case fatality,[1] mostly attributable to bronchopneumonia, from 7.0% in 1927–8 to 3.8% in 1935–6 would seem sufficient justification for hospitalization on this large scale. However, measles has shown in the past half-century a remarkable decline in severity, so that deaths, allowing for changes in the child population, are now about one-quarter of what they were as recently as 20 years ago.[2] The most important contributory factors to this sharp fall have probably been improved standards of nutrition and hygiene and, since 1936, the use of sulphonamides for the treatment of secondary bronchopneumonia and sepsis. The reduced incidence of serious lung complications lessens the need for hospital treatment, and it is possible that the patient with uncomplicated measles may be better off at home.

In recent years the commonest complication of measles nursed in L.C.C. hospitals has been otitis media.[1] The mucosa of the upper air passages after attack by viruses like those of the common cold, influenza, measles, and even rubella,[3] is particularly susceptible to secondary bacterial infection. The risk of acquiring such infection is obviously much greater in a hospital ward, where there already are many streptococcus-infected patients, than in the home, where exposure to a streptococcus carrier will be fortuitous. In the 1914–18 war measles complications—e.g., pneumonia, empyema, and otitis media—were frequent and severe among American troops nursed in hospital, and were largely due to the haemolytic streptococcus. Further, the likelihood that the streptococcus was being transferred from patient to patient in hospital was indicated by an increase in streptococcal-throat carriers from 11.4% on admission to 56.8% 8 to 16 days later.[4] Conclusive proof of streptococcal cross-infection in a measles ward was first provided by Allison and Brown,[5] who, using streptococcus typing as they had earlier done in scarlet-fever wards, found a secondary-infection rate of 51.2% and an incidence of 19% of suppurative otitis media as a result of streptococcal cross-infection. Their results were confirmed last year by Wright, Cruickshank, and Gunn,[6] who found that, despite an 18.2% carrier rate of various streptococcal types among new admissions to a measles ward, secondary bacteriological infection (73.3%) and suppurative otitis media (18.3%) were attributable to the spread of a single streptococcus type. Thus, in addition to the exposure to a heavily infected environment, the hospital patient is also at the mercy of streptococci that may have acquired the capacity of invading human tissues. Even sulphonamide prophylaxis and therapy may be impotent, for Wright and her colleagues found that their epidemic strain was sulphonamide-resistant.

In a further examination of the problem (see page 285) Joyce Wright has applied the knowledge gained from a detailed bacteriological and clinical investigation in one measles ward to a critical analysis of the complications occurring among measles patients admitted to one hospital during the 1942–3 epidemic. On the justifiable assumption that otitis media occurring after the fifth day in hospital was mostly due to cross-infection, irrespective of a previous history of middle-ear disease, 13.3% of 478 patients acquired this infection in hospital, whereas early otitis media, possibly due to an organism already present on admission, occurred in only 3.6% of cases. The incidence of otitis media in this series showed little difference in children up to 9 years of age, but 11 of the 14 mastoidectomies were done in children under 3 years of age; and children under 1 year were particularly liable to develop severe complications. A point of some importance was that secondary infection dropped sharply in April and May, when, with warmer weather and longer days, natural ventilation was better, while with the waning of the epidemic, bed-spacing could be increased. The temptation to add a few extra beds to a ward during the height of an epidemic must be strenuously resisted by hospital authorities, for in the end it serves no good purpose. Complication rates are increased, the average stay in hospital is prolonged, isolation accommodation is overtaxed, and the turnover of patients is slowed down rather than accelerated. Even with little overcrowding Wright has shown that cross-infection among measles patients in one hospital in one season resulted in an additional 432 weeks in hospital at an estimated cost of over £2,000. Early discharge may seem one way of avoiding the hazard of secondary infection, but as nearly half the cases become bacteriologically cross-infected in the first week, and over three-quarters by the end of the second week, the early-discharged child may be sent home to develop otitis media there rather than in hospital.

This frank analysis of the effects of admitting cases of uncomplicated measles to hospital needs the most careful consideration of practitioners, medical officers of health and hospital authorities. Obviously in wartime, when mothers are employed on war work, many young children with measles cannot easily be nursed at home. If for that reason, or because home conditions are bad, or the child is seriously ill, the patient must be removed to hospital the hospital administrator must take all possible precautions to minimize the risk of cross-infection. Most important of these are adequate bed-spacing (144 sq. ft. per bed) and optimum ventilation. Good ventilation, with windows partially bricked up, may not be easy just now, but Florence Nightingale's dictum that "windows were made to be opened" is not preached or practised enough. Next in importance is probably dust-suppression measures. Though the importance of dust-borne infection and the practicability of oiling floors and bed-linen as an antidote have lately been questioned[7], a cross-infection rate of 18.6% and an otitis incidence of 2.8% in an "oiled" measles ward, compared with figures of 73.3% and 14.3% respectively in an unoiled ward, indicate that this method of control deserves extended trial. Oiled floors alone are not effective, but a practicable method of oiling bed-linen has been described in our columns.[8] Other important prophylactic measures are the removal from the measles ward of children with suppurative complications and reserving isolation accommodation for young children, particularly those under a year, and those with a previous history of ear-discharge. Most practitioners are aware of the desirability of home nursing of measles wherever practicable; fewer, perhaps, know that when measles is introduced into a household by a child at school the pre-school children may, after a prophylactic injection of 5 to 10 c.cm. of adult serum, develop an attenuated attack which reduces to a minimum the risk of complications. Convalescent measles serum, of which supplies are limited, should be reserved for the protection of sick and very young children. This subject is fully dealt with in an excelent review of the disease by R. E. Smith.[9] A new development is Cohn's globulin fraction, containing natural antibody, concentrated 10 to 30 times, which in remarkably mall doses has already been used successfully in America or both the prevention and the attenuation of measles.[10] Thus measles should soon become, what in the past it has ometimes been erroneously called, one of the minor maladies of childhood.

PAIN, FEAR, AND FATNESS

ymptoms were succinctly defined by James Mackenzie s disturbed reflexes. Often antedating physical signs, ey may point to the seat of the disturbance while it is till in the recoverable stage. A recent symposium[11] on eir analysis and interpretation emphasizes their importance. Of all the symptoms which cause patients to seek edical aid the commonest are pain and fear. The estimaon of pain is elusive, not only because it is purely subctive, but because it may be referred elsewhere than to e site of the trouble. Referred pain is, however, fairly ell understood, thanks to the classical researches of ackenzie, Ross, and Henry Head. More difference of pinion has existed as to the sensitivity of the deeper strucures to painful stimuli; but most observers agree with urst that this depends on whether the stimulus is the appropriate one and that tension is the most effective cause in a hollow viscus. This accords well with the more recent observations of Sir Thomas Lewis on accumulation of metabolites as a cause of pain. Half a century ago Michael Foster in his Rede Lecture on "weariness" indicted metabolites as a cause of fatigue, and Lewis has postulated the liberation of some chemical substances as the cause of painful sensations in the skin. Now he extends this idea to include Foster's in an interesting manner. A fundamental observation of his, in conjunction with Pickering and Rothschild,[12] must be quoted to make this clear. They applied pressure to an arm by a blood-pressure cuff and noted the occurrence of intolerable pain 70 seconds after exercise was begun. When the exercise stopped short of causing pain, no pain subsequently occurred, although arterial occlusion was continued and anoxaemia was thus maintained. Thus it would appear that during exercise pain-producing metabolites are formed, which anoxaemia alone does not do. The inference was drawn that accumulation of metabolites in tissue spaces may be responsible in general for the production of pain. Katz[13] and others applied these findings to the causation of cardiac pain, the ischaemia of the myocardium (which must continue its activity) leading to accumulation of metabolites, whether momentarily as in angina, or prolonged as in coronary thrombosis. Muscular tension, suggested by Hurst as a cause, is capable of a similar interpretation. It may be observed that this theory seems the more probable on two grounds. Now that we know, thanks to Loewi and to Dale, that there are chemical intermediaries between the nerve-endings and the tissue on the efferent side, it would not be surprising if the same rule held on the afferent side. Again, Wilfred Trotter in his Huxley Lecture pointed out that naked sensory nerve-endings, such as in the cornea, carried only painful sensations, while the various forms of touch corpuscles allowed of discriminative sensations which had a higher threshold than that of naked endings, but which on more powerful stimulation gave rise to pain. It is clear that a chemical pain-producing substance would affect a naked nerve-ending more quickly than one wrapped up in a protective covering, but, given sufficient liberation of such a substance, it could soak through the covering, thus exciting pain. Nor does all this conflict with Adrian's discovery that nerve fibres carrying painful sensations are of smaller calibre and slower to convey impulses than other sensory fibres. On the basis of these and other observations the symposium throws new light on the causes of pain, whether in head, chest, abdomen, or joints; it also brings a new interpretation of the effect of rest on pain and explains why pain persists after cessation of the exciting cause.

Though fear often drives the patient to the doctor, it may keep him away lest his suspicions may be confirmed. Thanks to the work of W. B. Cannon and others, we now realize how fear can be translated into a number of physical symptoms due to emotional excitation of the sympathetic nervous system, which call for careful analysis by the physician in order to detect their real cause. Another problem often facing the practitioner is fever without physical signs, the difficulties of which are fully discussed. The plan here adopted lends itself less satisfactorily to the discussion of such topics as jaundice and melaena, where the objective element is more obtrusive. The closing discussion on obesity, however, contains many points of interest.

American physicians and life offices have always taken a gloomy view of the prospect for the obese, but in this climate the "fair round belly" not infrequently survives into the "lean and slippered" stage. Herein it is laid down as an axiom that "a plethora of calories is the explanation of obesity, all the protestations to the contrary notwithstanding," for the law of conservation of energy must apply here as elsewhere. But it is admitted that the difficulty remains of explaining why on the same diet one individual remains thin and another puts on weight. This difficulty is increased when it is found that the basal metabolic rate of a fat man is higher than normal. True, this is attributable to the fact that his surface is larger, but it also implies that he is using up more energy, and still remains fat. To talk of "lipophilia" is reminiscent of the "dormitive" property of opium, and is no explanation at all. That a disturbance of the hypothalamus may be associated with gross obesity is now recognized, but it is still difficult to explain how this operates. Of the various hypotheses here put forward, two deserve further consideration. In some cases a disturbance of water balance may originate in the hypothalamus and, acting through the pituitary, lead to retention of water in the tissues. In others there seems to be overproduction of insulin, which leads to ingested carbohydrate being assimilated too rapidly. As the capacity for storage of glycogen is limited, the remainder is converted into fat. In such subjects there is at first a tendency to show a low level of blood sugar and increased tolerance for sugar. This theory would explain the well-known fact that the obese subject is liable to glycosuria in later life—when the overworked pancreatic islets become exhausted. There are in some cases other endocrine and psychological factors which need not be considered here, but it seems to us the final advice that has to be offered to many of these patients is that the choice lies between being stout and well or being thin and ill—a discouraging outcome from so much research.

TRAINING OF PSYCHIATRISTS

The second interim report of the Committee on Psychological Medicine of the Royal College of Physicians of London begins by pointing out the inadequacies of the requirements for the present diploma in psychological medicine. The committee recommends instead a five-year course of study and clinical and laboratory work after one year in a general hospital as house-physician; this period would allow for the diversity of experience that is now necessary for the psychiatrist, and is intended, as the report points out, to try to prevent the tendency for psychiatry to be split up into a series of specialties, the practitioners of each of which tend to drift apart and to have little in common in their points of view. No course, however comprehensive, can cover everything in a completely satisfactory way, and perhaps the main thing to be regretted in the recommendations is that it was not thought possible to assign more time than three months to the study of psychology, the principles and methods of which are of both general and particular value for the psychiatrist as well as the non-medical psychologist. The committee is well aware that such a curriculum as it suggests can be brought into effect only gradually, and also that the embryo psychiatrist may have some difficulty in financing himself during the period. It hopes, however, that it may be possible to arrange this during the greater part of the time he holds paid appointments. The old question of uniformity in the standards demanded by the various examining bodies is also dealt with, and the R.C.P. report in itself should have considerable influence in bringing about a satisfactory solution of this problem.

IS TUBERCULOSIS SPREAD BY DUST?

The correspondence about the risk incurred by girls, particularly if they are Mantoux-negative, of acquiring tuberculosis in the nursing of tuberculous patients raises the question of how this infection may be spread in hospital wards. At the end of last century Flügge and his associates showed how difficult it was to infect guinea-pigs by inhalation of dried sputum, whereas animals exposed within a yard of a coughing tuberculous patient could be infected more easily. Since then more than one investigator has tried to infect guinea-pigs by exposing them for days or weeks in tuberculosis wards, usually with negative results. Yet in view of recent evidence of dust-borne streptococcal infection the possibility of acquiring tuberculosis by the inhalation of infected dust from floors and blankets must be looked into again. Attempts by some investigators[1] [2] to isolate living tubercle bacilli from the dust of tuberculosis wards have yielded surprisingly poo results, as opposed to the experience of Cornet and others The chances of success turn upon the viability of th tubercle bacillus, the amount of ventilation and daylight and probably to a less extent on the temperature an humidity of the ward. Sunlight has long been accepted a rapidly bactericidal to tubercle bacilli in exposed sputum Smith[2] has shown that unfiltered daylight is also an activ bactericide against dried tubercle bacilli, so that in "th dosages in which they may be spread by trained patient in well-run institutions they probably do not survive i infectious quantities more than a few hours." In hi experience dried tubercle bacilli in varying dosage survived the bactericidal action of a north light for periods o four hours to five days, whereas in the dark they remaine viable for one to five months. Garrod[3] has lately prove that daylight through glass is also bactericidal. Thus th well-lit, well-ventilated ward is unlikely to facilitate th spread of dust-borne tuberculosis.

Another argument that may be used against the chance of dust-borne tuberculosis is based on the finding that onl very fine particles, of the order of 5 μ diameter, can b aspirated directly to the alveolar space.[4] Thus if tubercl bacilli must reach lung parenchyma before they can initiat infection, coarse dust particles would, even if contaminate with bacilli, be filtered off in the upper air passages. However, Lurie[5] has shown that guinea-pigs and highly susceptible rabbits may be infected from cage-dust and can b protected against this by a screen of ultra-violet light. is possible, therefore, that fine dust—e.g., from blanke —may be a source of infection to the nurses. If this b so it might be advisable for nurses to wear efficient mas when making beds in tuberculosis wards. Alternativel the bed-linen and floors of the wards could be treated wi oil.[6] But the main source of infection is probably t fine droplets expelled by the patient during coughing a loud vivacious talking. Coughing is remarkably rare in the well-run sanatorium for early cases. It is much more common in the chronic tuberculosis wards of a general hospital, where the risk to probationer staff is probably greatest. Much more could and should be done to eliminate this source of infection by training the patient to avoid unnecessary coughing and to use his handkerchief to prevent the dissemination of infected spray. As some of our correspondents point out, the risk of infection in tuberculosis wards can best be minimized by instruction of nurses in the probable sources and modes of infection and by the maintenance of high standards of hygiene for patients and staff alike.

SOVIET GRAMICIDIN

Penicillium notatum and other fungi are not the only kind of micro-organism producing a substance highly lethal to other species and capable of use as an antiseptic. It is now nearly ten years since Dubos extracted such a substance from cultures of an aerobic sporogenous bacillus, *B. brevis,* and called it gramicidin, from its remarkable lethal action on the Gram-positive pyogenic cocci. This substance was later found to contain two elements: one to which this action was mainly due, and another, tyrocidine, which also killed Gram-negative bacteria and was more toxic to mammalian cells. It is now thought that the two should be used in combination, and such a product is now available commercially under the name of tyrothricin. There have been favourable reports on its use as a local antiseptic for a variety of purposes. Meanwhile, G. F. Gause and M. G. Brazhnikova of the Institute of Tropical Medicine, Moscow, have examined several hundred strains of aerobic sporogenous bacilli cultivated from Russian soils, and discovered one which produces an antibacterial substance, to be named "gramicidin S" (Soviet gramicidin), which differs from tyrothricin, though it is of similar composition and action. The properties of this substance and its clinical use have now been described in both the American[1] and English[2] medical press. Extraction from cultures is a simple process furnishing a high yield of a single readily crystallizable substance, having a much higher melting-point (268–270° C.) than either constituent of tyrothricin; like these substances it is a polypeptide, but differs in the number and proportion of its amino-acids. It contains a high proportion of leucine—a fact of some interest in that S. W. Fox *et al.*[3] have been studying isomers of leucine with a view to determining the nature of the action of antibacterial polypeptides. They find that *d*-leucine inhibits *Lactobacillus arabinosus,* whereas *l*-leucine is a factor required for the growth of this organism—a relationship strongly suggestive of the sulphonamide type of effect.

Gramicidin S acts on a wide range of bacteria, including Gram-negative species, and is very highly active—more so than tyrothricin—against staphylococci. Experimentally it has been shown to have a prophylactic action against gas gangrene; it would have been interesting if some other antiseptics had been employed in these tests for comparison. Clinically it has been used successfully in both the prophylaxis and treatment of wound infections, and in treating osteomyelitis, empyema, and certain skin infections. Its toxicity is about equal to that of tyrothricin, which means that it is suitable only for local application, though the injection of a fairly large quantity into a closed cavity, such as an empyema, has evidently no ill effects. Has this kind of biogenic antiseptic any future, assuming that penicillin, which vastly excels it in some of its properties, will soon be freely available? The answer seems to be that it has one certain and one possible advantage over penicillin. The former is its action on Gram-negative bacilli (*Proteus* and *Bact. coli*; no data mentioned for *Ps. pyocyanea*), since against these penicillin is powerless. The possible advantage is greater local persistence owing to its high degree of insolubility; whether this in fact occurs cannot be deduced from the available information.

MEDICAL MISSIONS

Some interesting figures about medical missions are given in a report under the title of *Manpower in the Twentieth-Century Church*[1] which was presented not long ago to the Assembly of the Church of England. The author, Canon J. McLeod Campbell, general secretary of the Missionary Council of the Assembly, states that before the war, taking all Protestant denominations, 900 missionary doctors were at work, one-third of them women. Of this total 282 were from Great Britain and 416 from North America. This small band of medical missionaries is outnumbered by the doctors who, under the auspices of missionary societies, are serving in their native countries; the indigenous force numbers some 1,350. There are fewer Western missionary doctors in China than Chinese, and fewer Western doctors in India than Indians. The same holds true of nurses. Over 1,200 nurses have gone out from Western countries, but the number of nurses (one-third fully qualified and the remainder student nurses) who are on missionary service in their native countries is ten times as great. African nurses are in a majority of 1,025 to 400 Western nurses in Africa. The growth of indigenous medical missions is all to the good. The medical missionary may well be content to see his labours taken over by doctors from the people whom he has served.

The same report discusses the incentive to medical missionary work. The choice presented to the ordinary layman as between the continuance of his secular calling and a missionary career may be a hard one, but it is not unduly complicated. On the other hand, the medical man may well reply to his conscience that his services are needed at home, especially during the present shortage, where they are of the same quality and value and urgency as in the mission field. The testimony of various medical missionaries is cited in this report as to the adventure of their calling, the richness of clinical experience which it offers, and the opportunities for research. No doubt all that is true, but it is an insufficient incentive. The real motive must be a profound sense of service. One medical missionary in Nyasaland is quoted as saying, "Dirty, lonely, unpleasant, uncomfortable service, the mission hospital stands for that. We are primarily practical workers to demonstrate Christianity in action in daily work." Medical missions may be expected to appeal to an increased number of medical men and women returning from the war. The only counsel that can be given them is that they must be sure of the reality of individual vocation.

The Medical Research Council has appointed Prof. A. A. Miles, F.R.C.P., of the Chair of Bacteriology at University College Hospital Medical School, to its staff at the National Institute for Medical Research from Oct. 1, 1945, with a view to his becoming Director of the Department of Biological Standards on the retirement of Sir Percival Hartley, F.R.S., next year.

THE EDINBURGH OUTBREAK OF SMALLPOX, 1942

BY

C. KILLICK MILLARD, M.D., D.Sc.
Past-President, Society of Medical Officers of Health

I have recently received, through the courtesy of the M.O.H. for Edinburgh (Dr. W. G. Clark), the official report on the outbreak of smallpox which occurred in that city towards the end of 1942. There has been so little major smallpox in this country during the past 40 years that any important outbreak is worth reporting upon fully, and this has certainly been done as regards the one in question; for although the total number of cases was only 36, the report extends to 90 closely printed pages, and few material aspects of the outbreak or of the great vaccination drive which attended it have been omitted. The report is a model of careful writing and a painstaking record of the great amount of administrative work entailed.

Brief Outline of Outbreak

The outbreak began at the end of October and terminated at the end of December. It was practically all over in a matter of nine weeks. Dr. Clark and his staff deserve hearty congratulations on achieving such a highly satisfactory result. The outbreak was presumably linked with the one which had occurred in Fife in, August–October and which was just coming to a close. That in turn was presumably linked with the, ship-borne outbreak in Glasgow earlier in the summer, though in neither case could any direct connexion be discovered.

The first of the Edinburgh cases occurred in a patient in the Edinburgh Royal Infirmary—a miner, aged 46, who had been a patient in the institution since Oct. 5. He sickened on the 23rd and the eruption appeared on the 27th—22 days after his admission. It is clear, therefore, that he must have been infected while in the Infirmary. It is noteworthy that this man had been vaccinated in infancy and again during the war of 1914–18, and had good foveated scars. Although a moderately severe case, it was modified in character. It was diagnosed as chicken-pox, and as such was transferred to the Edinburgh City Hospital, where that diagnosis was at first tentatively accepted. The case was not finally diagnosed as smallpox until Nov. 1.

On Nov. 1 a second case—that of a boy, aged 12, who from Oct. 15 to 29 had been a patient in the same ward at the Royal Infirmary as the first case—was admitted to the City Hospital with smallpox. He had sickened on the day on which he had been discharged from the Infirmary, and the rash had appeared on the 31st. The boy had never been vaccinated and the attack proved fatal.

During the first week in November further cases of smallpox occurred in three medical students who were attending the Royal Infirmary, and in six patients in the convalescent home to which patients are transferred from the Infirmary. There were three other cases in patients who had been recently discharged from the convalescent home, thus making a total of 14. It seems clear that all these cases were traceable, directly or indirectly, to some source of infection in the Royal Infirmary. The report suggests as the most probable explanation a "missed" case, but though careful search was made no such case could be identified. Assuming that the source of infection was a "missed" case—and certainly this is the most likely explanation—it was probably a very mild modified case with trivial symptoms and a few insignificant spots, occurring in a vaccinated subject (possibly another medical student), such as has so often been the cause of outbreaks of smallpox in the past.

The Mass-vaccination Campaign

Once the presence of smallpox in Edinburgh was recognized the usual routine measures for dealing with the disease, which have now become universal in this country and which have proved so remarkably successful if efficiently carried out, were put into operation. But the authorities decided that this was not enough. They had before them the example of the neighbouring city of Glasgow, where, a few months earlier, a mass-vaccination campaign had been carried out on a very great scale, and, *as it was then assumed*, had promptly brought the outbreak in that city to an end. Certainly, within a week or two of launching the campaign all further cases of smallpox in Glasgow had ceased. The personal attitude of the M.O.H. for Edinburgh is indicated by a passage in his preface to the report, where he writes: "The protection afforded by vaccination renders specific inoculation the sheet anchor in controlling the disease in the presence of an outbreak." Accordingly, without losing any time, and without waiting to see whether the routine measures taken were likely to control the outbreak, a mass-vaccination campaign of the whole general population—with all that such a measure inevitably entails in the way of painful arms, temporary illness, interference with work, general upset, and widespread scare, even risk of a certain number of deaths—was decided upon, and on Nov. 8 22 vaccination centres were opened in various parts of the city.

Was the Vaccination Campaign Really Necessary?

The object of the present article is to suggest that this serious step was not really necessary or called for. For an outsider to make such a suggestion is of course a thankless and seemingly ungracious task, but if the example of great cities like Edinburgh and Glasgow is allowed to go unchallenged it is only to be expected that other places where one or more cases of smallpox may happen to occur will be encouraged to do likewise.

As regards Glasgow, the matter has already been dealt with (*B.M.J.*, 1943, **1**, 288), and it was then shown that the outbreak in that city was really over before the vaccination campaign was even started, and therefore that no claim that it was the campaign which brought the outbreak to an end can be substantiated. It is now suggested that the same consideration applies to the Edinburgh outbreak also.

The relevant facts, as stated in the report, were as follows: From Nov. 1, when the first case was diagnosed as smallpox, up to and including Nov. 7, 14 cases of the disease had been discovered, all, as we have seen, apparently connected with an undiscovered source of infection in the Royal Infirmary. The mass-vaccination campaign was actually started on Nov. 8, but we are not told when the decision to take this drastic step was really arrived at. In view of all the arrangements which had to be made, one may assume that it must have been decided upon some days prior to Nov. 8, when the number of cases which had occurred would be less than 14. Four cases had been admitted to hospital on Nov. 7, three on the 6th, and three on the 5th. It looks, therefore, as if the decision must have been arrived at almost at the very outset, when only some half-dozen cases or less had occurred. The authorities were, of course, quite right to treat the outbreak as serious; and in the old days, before modern methods of control were possible, when there was no notification of disease, practically no hospital isolation, and no skilled sanitary staffs—not even medical officers of health—such an outbreak would probably have become a widespread epidemic. But what really did happen in this outbreak which we are now considering? If we classify the 36 cases into weeks according to the assumed date of infection (the dates are given in Appendix I of the report, calculated as being 14 days before the appearance of the rash) we get the following table. (By taking the date of infection rather than the date of removal to hospital one gets a truer picture of the progress of an outbreak, as it cuts out the time-lag between the date of infection and the date when a case can be recognized as smallpox.)

Smallpox Cases arranged in Weeks according to Date on which Infection was Contracted

Week	Cases Infected
1 (Oct. 12–18)	2
2 („ 19–25)	14
3 („ 26–Nov. 1)	7
4 (Nov. 2–8)	2
Vaccination campaign started on Nov. 8	
5 (Nov. 9–15)	5
6 („ 16–22)	0
7 („ 23–29)	4
8 („ 30–Dec. 6)	1
9 (Dec. 7–13)	0
10 („ 14–20)	1
Total	36

Will any unbiased person looking at this table seriously suggest that it affords support to the contention that it was the vaccination campaign which brought the outbreak to a close so speedily and satisfactorily? Compare it with a similar table for other outbreaks—e.g., that in the Home Counties in the early part of 1944, where no comparable vaccination campaign was undertaken—or with the one at Glasgow, which, as has been shown, was over before the campaign began; or with the one in 1903 in Leicester, where, in a practically unvaccinated population, the weekly number of cases fell from 48 to 22, 14, 10, 4, 2, 1, in successive weeks. I submit that in all probability an almost identical result would have been attained if the Edinburgh vaccination campaign had never been embarked upon. Indeed, one cannot help thinking that if only the campaign had been deferred for a week or ten days it would never have been launched at all.

Objections to a Vaccination Campaign

It is not as if vaccination were a trivial operation comparable, say, with immunization against diphtheria. On the contrary, it entails definite illness in a substantial number of cases. The report states that it was not possible to assess the proportion of vaccinations which were attended by "severe" reactions, but from what we know about vaccination, even when performed under the most favourable conditions, we may assume that the total number was considerable,* and doubtless entailed a good deal of interference with work as well as much personal suffering. The psychological effect of a mass-vaccination campaign is also an important factor which should not be ignored. Then there is the risk, now definitely recognized, of that serious complication, post-vaccinal encephalitis. The Edinburgh campaign resulted in 22 such cases, with 8 deaths. The total number of deaths due to vaccination was 10. Incidentally, the number of deaths due to smallpox was 8, only two of these being in unvaccinated subjects.

There would still seem to be some who think that in dealing with smallpox their motto should be, "The more vaccination the better." Years ago I remember being told that the control of smallpox could be summed up in three words—"Vaccinate, vaccinate, vaccinate!"; also that "every individual you can get vaccinated is a brand snatched from the burning." The "sheet anchor" simile was very popular in those days. But, when all is said, it cannot be denied that vaccination is only the lesser of two evils. Surely, then, our motto ought rather to be, "The *less* vaccination the better, so long as we can achieve our object, which is the effective control of smallpox."

In a paper read at a health congress 42 years ago (Exeter, 1902) I wrote these words, which perhaps are worth repeating:

> "It must never be forgotten that vaccinia is, after all, a disease, and those of us whose profession it is to prevent disease should be ready to abandon it at the earliest possible moment consistent with the public safety. The control of disease by the substitution of one disease for another, whilst it may be expedient, can never be regarded as an ideal method."

It only remains to say that the total number of persons vaccinated during the Edinburgh campaign was estimated at 254,000, to which must be added an estimated number of 20,000 vaccinated earlier in the year as the result of the scare caused by the limited outbreak in Glasgow. As, however, the population of Edinburgh is 440,000 there were still a very large number of unprotected persons remaining in the city, even allowing for those (mostly young children vaccinated in infancy) who were already protected by recent vaccination. Therefore, if the outbreak had "wanted" to spread there would still have been plenty of susceptible material for it to work upon.

Postscript.—It is interesting to note that of the three medical students who fell victims to the disease one had been vaccinated in infancy, another had been vaccinated in infancy and again in 1927; while the third had been vaccinated in infancy, again in his school days, and a third time in 1940–4. In this last case the "sheet anchor" seems to have dragged somewhat! A cynic might suggest that another metaphor would be more appropriate.

WITH THE F.A.U. IN CHINA

The work of the Friends' Ambulance Unit where fighting is hardest and where living conditions are the most difficult is too often taken for granted. It is right, therefore, that we should be reminded from time to time of the work the Unit does behind many battle fronts, and one such reminder has just reached us in the form of a report on the medical work of the F.A.U. with the Chinese Army in 1944, from which the following facts have been taken.

Military Medicine and Surgery

Some 40 members of the F.A.U., including nine doctors and nine State-registered nurses of American, British, and Chinese nationalities, have provided a number of medical and surgical teams in the field as part of the Chinese Red Cross programme. At the beginning of 1944 there were three teams—at Yungping, Yenshan, and Tengchuan. The first of these, at a divisional field hospital at Yungping, was to begin with mostly concerned with treating medical cases. During the first three months of the year over 7,000 out-patients were seen, and some 250 in-patients. Later the division went into action, and the team moved with it to do first aid and emergency surgery close to the fighting line. The need for maximum mobility in country without roads meant travelling with a minimum of personnel and medical equipment. Living conditions were often very primitive, and the fact that the campaign was conducted during the monsoon did not improve matters. In one month 435 casualties with wounds in all parts of the body were treated. More exact figures of the work of this particular unit are not available owing to campaign conditions when the team acted as a C.C.S. during the siege of Tenchung.

Another team, numbering at times some eighteen members, including three doctors, was stationed at an intermediate hospital at Paoshan, which for some time was the principal receiving centre for a large sector of front. All surgical cases were referred to the team for examination and treatment, and although it was not possible to keep more than a percentage for operation, those likely to suffer serious aggravation of wounds by evacuation to the rear were admitted. In a two-week period in May 548 cases were admitted, of which 97 were kept for treatment; 75 operations were done during this period, chiefly for fractures and for removal of foreign bodies. During June 2,739 cases passed through the hospital, 208 of which were kept for observation. There were 138 operations. *X*-ray examinations numbered 130, not including those done in the theatre for the reduction of fractures, etc. In July the figures were 2,195 cases seen, 238 kept for special examination; operations 165, for fractures, extraction of foreign bodies, wound débridement, amputations, and rib resections. In August and September there was the same story of a stream of surgical cases being dealt with expeditiously by this team until October, when the numbers were somewhat fewer. A report of this unit's work for the remainder of the year is not yet available.

Surgical mechanics are now an integral part of the Unit. Three are engaged in making such things as artificial limbs, splints, special equipment for orthopaedic surgery, instrument sterilizers, washing equipment, delousing plants, hot-water systems, and in repairing instruments of all kinds—safety valves, power plants, operating tables, microscopes, and *x*-ray machines.

Medical Care of Civilians

Another side of the work of the F.A.U. in China is the medical care of civilians in districts without adequate facilities. One team was sent to a small town in South-West Yunnan, where the local hospital badly needed help. Here the incidence of malaria of all types was as high as 80%; indeed the incidence of diseases of all kinds was higher and they were more severe than in any other area of which the F.A.U. had had experience. The chief difficulty was, of course, communications. The quickest transport was over pack trails, and the journey took at least two weeks; the dispatch of supplies and the replacement of personnel were therefore problems of the first magnitude. To equip and supply even a small hospital under these conditions would have been an expensive and difficult undertaking, so that most of the work was confined to out-patients, many being visited in their own homes.

In reply to other appeals for help the F.A.U. sent a team to staff a hospital at Kutsing and also to start one in Tenchung after this place was reoccupied by the Chinese. The staff sent to Kutsing included two doctors, one or more trained nurses, a laboratory technician, and a business manager for work in the hospital. Although this arrangement was made for two months only, it has been extended by agreement to two years. The hospital is the only place between Kunming, 100 miles to the west, and Anshun, 250 miles to the east, where facilities exist for major surgery for other than United States Army personnel.

---

* H. J. Parish (*B.M.J.*, 1944, **2**, 782) analyses the results of 214 specially observed vaccinations in adults (Wellcome Laboratories staff) performed by the "multiple pressure" method, which it is claimed gives less severe reactions than the methods usually adopted in this country. He found that 9.8% had severe reactions. The total number of persons vaccinated in the Edinburgh campaign is given as 254,000, but this included some 58,000 children under 15 who had already been once vaccinated and in whom, therefore, severe reactions would be unlikely to occur. Deducting these we are left with 196,000. If we apply Parish's 9.8% to those figures we get 19,000 as the approximate number of persons who had severe reactions in the Edinburgh campaign

Mr. R. B. McClure directs the policy of the F.A.U. in China, and spends much of his time visiting the teams and directing their work.

MUNICIPAL SPECIALISTS

The inaugural meeting of the Association of Municipal Specialists was held on Jan. 19 at County Hall, London, with Dr. H. Joules in the chair. There was an attendance of more than 100. Dr. H. Joules was elected president, Dr. B. Barling treasurer, and Mr. G. F. Stebbing secretary. It was agreed that the objects of the Association should be as follows :

1. To improve the practice of medicine in all its branches in municipal hospitals.
2. To improve the status and promote the general interest of specialists employed by local authorities.
3. To provide opportunity for discussion on matters of professional interest and policy.
4. To promote good relations between specialists employed by local authorities and specialists working in voluntary hospitals and elsewhere.
5. To encourage professional communications between members and to arrange clinical or other meetings which may be considered to further the objects of the association.
6. To form regional branches of the association when the council considers them desirable.
7. To co-operate or amalgamate with, or become affiliated to, any other association or body not formed for purposes of profit, whether incorporated or not, whose objects are altogether or in part similar to those of the association.
8. To promote or oppose any legislative or other measures affecting any matters connected with the interests of the association.
9. To do all such other things as are incidental or conducive to the attainment of the above objects or any of them.

Communications to the Secretary should be addressed to 12, Manchester Square, London, W.1.

Reports of Societies

TREATMENT OF BREECH PRESENTATION

Among the papers read and discussed at the January meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland was one by Prof. J. F. **Cunningham** on the treatment of breech presentation.

Prof. Cunningham said that, for the mother and baby, the risks were greater than in vertex presentation. Before undertaking the delivery of a breech, especially in a primigravida, the obstetrician should have a complete and accurate knowledge of the important facts and details of the case. Careful observation of the progress of labour was also necessary. In breech presentations that persisted late into pregnancy certain causative factors should be looked for. He then discussed the mechanism of labour and the difficulties that might arise. If a breech presentation was discovered in the last few weeks of pregnancy, there was a choice of one of three procedures : (*a*) it might be left as it was and delivered as a breech, (*b*) it might be converted to a vertex, or (*c*) it might be delivered by Caesarean section. He discussed in detail the indications for each of these procedures. The slight risks of external cephalic version were more than compensated by its advantages. In his description of the conduct of breech delivery Prof. Cunningham mentioned the choice of anaesthetic, the method of delivery of the uncomplicated breech, the breech with extended legs, the impacted breech, and the breech with extended or nuchal arms. His practice was to give 5 units of pituitrin when the breech was about to be born in order to maintain the rhythm and force of the pains when they were most required. If the arms were extended it would be found easier, as a general rule, to deliver the anterior arm entirely first. The posterior arm might be delivered first in certain circumstances, but rotation of the body to bring the anterior arm posterior should not be done. Where difficulty arose in delivering the head, the application of forceps was considered safe. The forceps should not be removed until the head had been completely delivered.

General Discussion

The **President** (Dr. A. W. Spain) was in agreement with most of the things said. At Holles Street if they saw a breech presentation after the 32nd week version was performed. When a breech was fixed deeply in the pelvis of a primipara they frequently failed in the version. He agreed with Caesarean section when there had been long sterility. Dr. N. **Falkiner** considered that to extract a breech not impacted in a primigravida, without complete knowledge of the pelvic brim, was a hazardous undertaking. Dr. E. A. **Keelan** discussed the question of an anaesthetic when doing version. He did not think chloroform safe when given to a patient not in labour. Dr. T. M. **Healy** emphasized the point about the rotation of the baby in endeavouring to bring down the arms : any form of rotation should be avoided. He also agreed that version should be avoided in patients who had had adequately large babies by the vertex. He thought that the beginner would get into trouble if he delivered the anterior arm first in the ordinary case, where the baby was very large.

Dr. R. G. **Cross** stressed the importance of pelvimetry before version when the mother was a primigravida. He had been taught that external version under anaesthesia was contra-indicated, except in a young primipara with a degree of contraction of the pelvis, diagnosed by *x* rays, which would justify a trial of labour with a view to vaginal delivery. Why not give her progesterone instead of an anaesthetic ? Complications were apt to follow external version. He did not recommend the use of pituitrin by students before the placenta had left the uterus. Dr. F. W. **Doyle** pointed out that in the old days they were taught to convert a vertex presentation into a breech. Placenta praevia was often associated with breech presentations and he discussed the danger of causing post-partum haemorrhage. Dr. T. G. **Gallagher** held that the number of accidents to baby or mother in breech presentations was small and the dangers were exaggerated. He stressed the point that no attempt should be made in breech presentations to deliver the arms until the angle of the anterior scapula appeared in the symphysis, and that it was most important to have the occiput well down under the symphysis to deliver the head. Dr. **Margaret Nolan** said she had three times seen a uterus ruptured in consequence of giving pituitrin ; the babies died and one mother was lost. Dr. G. C. **Dockeray** thought pituitrin a dangerous drug and did not recommend its use by students.

Nova et Vetera

PRISONER-OF-WAR MENTALITY

Major Ellis Stungo, R.A.M.C., writes from C.M.H., Deolali, India Command: Apropos recent articles and correspondence in the medical press on "the prisoner-of-war mentality" the following extract from a diary published in London in 1788 may be of interest. This account relates to British officers captured by Hyder Ali and his son, Tippoo Sultan, in the Mysore Wars. The majority were taken prisoner at the Battle of Pollilur and incarcerated in the dungeons of the Island of Seringapatam.

> "While we were in this gloomy state of mind and ready to sink under the pressure of melancholy and black despair, behold, within the walls of our dismal dungeon, a Brahmin sent from Tippu Sultan, with a formal intimation of the final conclusion of peace—and that our irons were to be knocked off the next day. The emotions that sprung up on receiving this intelligence were so strong and lively, and raised to such a point of elevation and excess, as almost bordered on pain. The whole prison resounded with the frantic voice of a sudden as well as excessive joy and exultation. This tumult having in some degree subsided, though we were incapable of entire composure and rest, a proposal was made, and most readily embraced, to collect all the ready money in our possession, without the least regard to equal shares or proportions and to celebrate our approaching deliverance with some plaintain fritters and sherbet—the only articles of luxury we could then command, on account of our extreme poverty.

"By nine o'clock at night supper was announced, consisting of 50 dozen plaintains and a large chatty [pot] of sherbet. Every one being seated on the ground, the repast was received with utmost satisfaction. Toasts were drunk as long as our chatty stood out; and such was the agitation in our minds, that there was not one of us who felt the least inclination, or, indeed, who possessed the power to compose himself for sleep. We now waited with the utmost impatience for the return of the day and were impressed with a strong desire that our irons might be knocked off immediately.

"But to our great mortification, about seven in the morning, there arrived only one armourer. Every one struggled to have his fetters knocked off first. Promises, threats, bustling and jostling: every expedient that could be imagined were put into practice, in order to obtain that which would come unsought for in the course of a few minutes, or hours at least. The same men who had suffered the rigours of imprisonment, and the menace of a barbarous policy, with invincible resolution and patience as well as with mutual sympathy for years, were so transported by the near prospect of liberty, that the delay of a few moments seemed now to be more insupportable than even the tedious languor of our long, most alarming and anxious confinement."

Correspondence

Ovariotomy or Caesarean Section?

SIR,—Recently (Feb. 9, 1945) I gave an address on Caesarean section to the students of St. Andrews University, and when it came to a consideration of ovarian cysts complicating pregnancy I advocated that ovariotomy should be performed in preference to Caesarean section, no matter whether the operation was performed months, weeks, or days prior to labour or even during parturition. My object in writing now is to ascertain if this is the usual practice adopted by my colleagues, for I know that some stress the possible occurrence of intraperitoneal haemorrhage from the stump if ovariotomy be the operation chosen.

One of my former house-surgeons, who was candidate for a higher degree in obstetrics and gynaecology, performed ovariotomy three weeks before full term in a case where a dermoid cyst filled the pelvic cavity. This he did on my advice, when I assisted him at the operation. The examiner laid stress on the possible occurrence of haemorrhage from the stump, and stated that Caesarean section was preferable.

In the two maternity hospitals with which I am associated—namely, the County of Lanark Maternity Hospital at Bellshill and the Maternity Hospital, Motherwell—we have had six cases in the year 1944 where ovarian cysts complicated pregnancy. As I have been in active obstetric and gynaecological practice now for over forty years I have had ample opportunity of operating on this type of case, and in all, with one exception, ovariotomy was chosen in preference to Caesarean section, and in not one instance did haemorrhage occur from the stump. In the case where Caesarean section was performed the child was in a state of acute distress, as the patient had been in labour for two days owing to the obstruction caused by the ovarian cyst. It seems to me, therefore, that the risk of intraperitoneal haemorrhage has been exaggerated, and that the chance of this complication is less than that of rupture through a uterine scar in a subsequent pregnancy. In younger patients it is most desirable that the uterus should not be wounded. In all cases where ovariotomy had been performed shortly before delivery, forceps was applied during the second stage to ease strain on the abdominal wound. Rupture of the uterine scar in a subsequent pregnancy is a danger which must be borne in mind, and it may prove fatal before surgical aid is forthcoming.

I adopt ovariotomy for preference despite the fact that my experience of the Caesarean section operation is extensive and fortunate, as may be realized from the following record; for at the two hospitals mentioned above I find that 226 Caesarean sections were performed between Jan. 1, 1943, and the date of my lecture. There was only one death in the series, and that was in a case of placenta praevia where post-partum haemorrhage came on four hours after the operation. Post-partum haemorrhage should be considered as a menace in every case of placenta praevia. It is my belief that in a case of placenta praevia the classical operation should be selected in preference to the lower-segment operation. In this series of cases referred to I find that the lower and upper segment operations were performed in equal numbers in the hospital at Motherwell, while at Bellshill approximately one-third were lower-segment operations.

These cases were not selected. In many instances the patients were extremely ill. In one case the membranes had been ruptured for a week, and she had been in labour all the time; in two other cases a similar state of affairs had existed for five days. In one case of placenta praevia the patient lost such an enormous quantity of blood that it appeared in the corridor, having flowed across the labour-room floor. This patient was so ill that I performed the operation in her bed, and I attributed her recovery greatly to the administration of pentothal as an anaesthetic by the drip method. This method of anaesthesia was also chosen in a severe case of concealed accidental haemorrhage where the patient failed to respond to every restorative treatment. In none of the cases of concealed accidental haemorrhage was hysterectomy performed, as I consider that in such instances shock is one of the main dangers. No matter how damaged the tissues of the uterus appear, their recuperative powers are astonishing.

I would be interested to hear the opinion of your readers who are engaged in obstetric and gynaecological practice as to their method of dealing with cases of ovarian cyst complicating pregnancy, for evidently treatment by Caesarean section is a method recommended by some eminent authorities.—I am, etc.,

S. J. CAMERON.

Bellshill, Lanarkshire.

Investigation of Oestrogens in Cancer

SIR,—The Royal Society of Medicine has recently arranged for a scientific committee composed of the following Fellows of the Society to investigate the effects of oestrogens in cancer

Prof. E. C. Dodds (chairman), Dr. Alexander Haddow (vice-chairman), Dr. Frank Ellis (hon. secretary).

Sectional Representatives.—Experimental medicine and therapeutics, Mr. A. L. Bacharach and Dr. K. M. A. Perry. Obstetrics and gynaecology, Mr. Malcolm Donaldson and Mr. James Wyatt Pathology, Dr. W. E. Gye and Dr. R. W. Scarff. Radiology, Dr. Ralston Paterson and Prof. B. W. Windeyer. Surgery, Mr Rupert Corbett.. Urology, Mr. F. McG. Loughnane and Mr. Clifford Morson. Co-opted: Mr. G. B. Stebbing and Dr. A. B. Bratton, and Dr. K. Mather as statistical adviser.

The advisability of forming such a committee was considered by the Council of the Royal Society of Medicine after a preliminary investigation by the Radiological Section at 15 radiotherapeutic centres of the effects of stilboestrol in more than 100 cases of cancer of the breast (*Proc. roy. Soc. Med.*, 1944, 37, 731).

At its first meeting the committee decided to concentrate attention on carcinoma of the prostate, breast, and oesophagus, to confine the investigation to dienoestrol at two prescribed dosage levels, and to ask that records be kept on forms based on those of the National Radium Commission approved for use in the Ministry of Health's scheme for cancer. It was further decided that to avoid statistical difficulties the decision regarding the dose of drug to be used should be by random selection

This letter is inserted on behalf of the committee so as to provide an opportunity for members of hospital staffs who might wish to co-operate in this investigation to communicate with the undersigned.—I am, etc.,

F. ELLIS,
Hon. Secretary, Scientific Committee

1, Wimpole Street, W.1.

Penicillin: Price and Manufacture

SIR,—Dr. J. W. Shackle refers (Feb. 17, p. 232) to an article in the daily press quoting a case that had had about 900,000 units of penicillin and stating that the cost of this was £400. Dr. Shackle rightly demands that such an inordinate charge should be justified, believing that there is no valid excuse for the cost to be as much as one-tenth of the amount.

Dr. Shackle and your readers will probably be interested to learn that this cost is in excess by 1,000% and more of the price paid to those member companies of the Therapeutic Research Corporation producing penicillin under contract with the Ministry concerned, the plants of which members manufactured some 90% of the total quantity of penicillin manufactured in Great Britain during 1944. The cost of production in each of those plants and in all others is determined by the Ministry concerned after a cost investigation made in accordance with the usual procedure in relation to Government contracts. The precise cost varies, of course, from one plant to another due to the variations inherent in a biological process. There is not, and cannot be, any "penicillin ring" in this country to monopolize manufacture or to fix prices, whether inordinate or not, while a Government Department continues to take the entire output of all large-scale plants at a price determined for each plant by a cost investigation.

The machinery of the Therapeutic Research Corporation has facilitated close collaboration between its member companies in research to develop manufacturing processes for penicillin, but contracts to manufacture and supply to the Ministry have been placed with individual member companies and not with the Corporation. Several other firms in this country, in addition to member companies of this Corporation, are manufacturing or will shortly begin to manufacture penicillin under Government contracts, and while there has been close collaboration between the member companies of this Corporation and other manufacturers and academic workers, by exchanging and discussing information on research and development to assist in securing maximum production of penicillin for the nation in the least possible time, there has never at any time been any attempt by any of the firms to fix the price to be charged to the Government.

The Therapeutic Substances Act and Regulations ensure that there can be no monopoly, as commonly understood, in the manufacture of penicillin. It is open to anyone, firm or individual, to apply to the licensing authority for a licence to manufacture penicillin for sale, and provided the applicant satisfies the authority as to his competence to manufacture, and to control the purity and safety of, the product there is no reason to believe that a licence would be refused.

Despite the fact that Sir Henry Dale, President of the Royal Society and chairman of the General Penicillin Committee, told a press conference on Oct. 20, 1944, that "there is no substance in the talk about 'trade rings' in the manufacture of penicillin," suggestions that such "rings" exist in this country continue to be made, and we trust the information now given in this letter may once more assure your readers that there is no truth whatever in such suggestions.—I am, etc.,

FRANK HARTLEY, B.Sc., PH.D.,
Secretary, Therapeutic Research Corporation of Great Britain, Limited.
99, Aldwych, London, W.C.2.

Shock Therapy and Conditioned Reflexes

SIR,—Two very interesting résumés have appeared in your annotations "Neurone and Mind" (Feb. 3, p. 157) and "Shock Therapy and Conditioned Reflexes" (Feb. 10, p. 191). These two should be read together as they are complementary. It is always difficult to think of human behaviour in terms of the Pavlovian conditioned reflex, but if we can conceive of the engram as a complex of conditioned reflexes (laid down at an early age under the influence of emotion) and human behaviour as a complex of engrams, the relationship certainly becomes simpler. Prof. Berry pointed out: "Importance is attached not only to the mere existence of engrams but also to their proper order and sequence of their activities."

In the course of development of the child many patterns of behaviour (engrams) are laid down. Some become basic patterns and continue to be active throughout life; these are elaborated more and more to meet the greater demands dependent on the expansion of interests, while the others are relinquished willingly or with regret according to the affective value which they held for the individual. There are, during the course of development, many patterns which are in themselves contradictory, but not when taken in their context.

In the annotation on shock therapy and conditioned reflexes it is shown that shock will recondition a reflex in the absence of the conditioning factor. This certainly does throw a flood of light on this form of therapy and opens up avenues for speculation.

Can we assume that the effect of shock will be to recondition those patterns which at the time of their initiation had greatest affective value for the child and mobilize to a less degree those which are less concerned with the "vital interests"? This would seem to be the case, for it is known that shock therapy is most effective in the field of the psychoses, where the fixation point, or fault in development, is found to be at a very early age in the infant's relationship to his mother before the development of a cognate consciousness: the mother has never become for him a wholly good object which he can grasp and retain. From this is developed the fantasy of the "bad frustrating" mother, which, if left unaltered by reference to external reality, becomes a barrier to social development and tones the world as bad and hostile. It would appear that this reconditioning effect of shock has been to re-establish that first primitive good object relationship as it is of the greatest vital importance to his integrity.

It might be interesting to speculate that the effect of shock as a conditioner of reflexes varies in a direct ratio to the affective significance of the engrams involved. Unfortunately so far it would appear that there is no means of directing shock as to which series of engrams we should like reinforced. It should be possible, however, to evolve a form of therapy in which the "recall" properties of shock are combined with the selective facilities of the more orthodox psychological approach.—I am, etc.,

Bishop's Stortford. D. N. HARDCASTLE.

Therapeutic Sterilization in Mental Hospitals

SIR,—The Select Committee on Sterilization recommended in 1934 that operations for sterilization undertaken therapeutically for psychiatric reasons should not be performed in mental hospitals, as it was inadvisable that such a procedure should become associated in the public mind with these institutions.

It would be instructive to learn through the medium of your *Journal* what is the practice in this connexion in mental hospitals at the present time. The recommendation of the Select Committee appears to have indicated a "pre-treatment era" attitude towards the mental hospital. To-day, ten years later, a great deal of therapeutic work proceeds in our mental hospitals, and three queries arise in one's mind:

1. Ought *any* psychiatric therapeutic procedure to be placed outside the province of the mental hospital? Is there any basic difference between a salpingectomy in a patient whose fear of having further children is a potent factor in her mental breakdown and a prefrontal leucotomy in a patient whose depressive tendencies may cause him to take his own life?

2. If the answer to the above is in the negative, are not mental hospitals prolonging the days of their professional isolation by sending their patients to general hospitals for sterilizing operations? Is it not time the mental hospitals furthered their own cause by performing such operations on their own premises?

3. Why should the performance of such operations react unfavourably on the public attitude towards the mental hospital while apparently it does not do so in the case of general hospitals?—I am, etc.,

Carmarthen. A. M. SPENCER.

The Psychiatrist and the Psychologist

SIR,—I was interested in the annotation on psychiatrist and psychologist (Feb. 17, p. 229). It strikes me, however, that it is misleading in that it seems to imply that distinction between them is based upon a medical qualification, and that a trained psychologist who takes a medical qualification is thereby deprived of his status as a psychologist. This is a point which affects a large number of us. Many psychiatrists are also trained psychologists, and we resent, naturally, any suggestion that we cannot be both.—I am, etc.,

Plympton. H. W. EDDISON, M.D., D.P.M.

Supervision of Mental Defectives

SIR,—I am indebted to Dr. J. Johnston Mason (Feb. 3, p. 164) for supplementing my recent article by giving comparable figures for mental defectives from Brentry Colony. I feel that both sides of the picture are of equal importance, and serve to stress my appeal for assistance in finding suitable jobs for mental defectives, if necessary adequately subsidized, so that they may become as nearly as possible independent members of the community. Clearly the present increased employment of mental defectives is due to the labour shortage, and when the labour market becomes normal, then these men will once more become entirely dependent on the State unless some action is taken now to safeguard their future.—I am, etc.,

Gloucester. J. S. COOKSON.

Present Practice of Diphtheria Immunization

SIR,—It is disturbing to read in Dr. J. L. Blonstein's article on a wartime nursery (Feb. 17, p. 230) that out of 50 children under the age of 5, all immunized against diphtheria, 23 showed a positive reaction to the Schick test. Twenty-one of these had been immunized at "clinics," but there is no reason to suppose that immunization at a clinic would be less effective than that done elsewhere. We are not told (1) the age of the positive reactors; (2) whether a Schick test had been performed upon them three months after the immunization; (3) whether the mothers had been given a certificate (as is the practice in some boroughs) to show that the whole procedure was satisfactory at the time it was carried out. Nor are we told in which group of children the two cases of diphtheria occurred, and whether these were mild or severe cases.

Those of us engaged in infant welfare work and private practice are urged to carry out both immunization and propaganda, but reading an article with the above facts makes one wonder whether the present practice is as satisfactory as it should be, or whether a further Schick test should be carried out, say, at the age of 3, in addition to the test which is usually done three months after immunization. It would be interesting o hear the views of those who undertake this work on a large scale.—I am, etc.,

London, N.W.8. EVELYN MACLAGAN.

Retention of Urine

SIR,—During my time at Nagpur it was one of my duties to arrange for the training of medical licentiates at the Mayo Hospital. These students, both graduates and undergraduates, had to be taught how to relieve retention of urine in the male without causing unnecessary damage to the urethra. Many of he cases of retention of urine which came to the hospital were of a difficult and serious nature owing to the prevailing neglect of proper treatment of gonorrhoea. I found Phillips's filiform bougies and follow-through catheters (obtainable from Messrs. ynard, Paris) invaluable for many cases. Unfortunately, gum-lastic articles do not keep well in the climate of the Central Provinces, and they are difficult to sterilize in the out-patient department. It was with great interest that I read the note by Mr. Milroy Paul in the *Lancet* of Sept. 7, 1935, on his urethral bougie and catheter combined:

> "This set of bougies was made to my design by Messrs. Down Bros., London, to obviate the necessity for passing a metal catheter n dealing with that common emergency, acute retention of the rine from stricture. The bougies have the shape of Lister's bougies nd, in addition, a narrow channel running through their long axis. he bougies have proved very satisfactory in practice, as they are assed more easily than a metal catheter owing to their greater eight, better balance, and their bulbous ends, and I also prefer to se them instead of a metal catheter in cases of enlarged prostate, here occasionally it is necessary to use a metal catheter to relieve cute retention."

I was about to order a set when I read the note by Mr. Harold Dodd in the *British Medical Journal* (July 13, 1935) on his ister's bougie and dilating sound with Béniqué's curve:

> "In a ten-years experience of dilatations of urethral stricture I ave found that certain obstructions can only be negotiated by a ister bougie, while to pass others the curve of a Béniqué instrument is necessary. In using the otherwise excellent French bougie e absence of the graduated shaft and of the weighted handle of the ister pattern was repeatedly felt, and out of this arose the idea combining the two instruments in one in order to secure the lvantages of both. A graduated set, made for me by Messrs. Down os. and Messrs. Lewis Brothers, has the peculiar curve of the niqué bougie, with the olive-headed tip, neck, tapered shaft, eighted handle, and sizes of the Lister instruments. I have used it gularly for eighteen months and have found that it fulfils its purse well. It usually 'falls in,' the dilatation is gradual, and it is fective in passing a tortuous urethra. In addition, it is very useful r determining the patency of the common bile duct into the odenum, and for stretching the ampulla of Vater."

Messrs. Down Bros. have prepared for me, out of polished nickel-silver, which is slightly heavier than steel, a set graduated from 5/8 to 15/18 combining the ideas of Mr. Harold Dodd and Mr. Milroy Paul. (A spigot and stylet are also supplied.) These central-channelled sounds are easily sterilized, and as they are not plated in any way the danger of causing a slight tear in the mucous membrane of the urethra is obviated. They can, preceded if necessary by the smaller sizes of Mr. Harold Dodd's bougie, be used for relieving most cases of acute retention of urine and are suitable for dilating almost every kind of stricture. After the sound has been passed and before it is withdrawn the bladder can be filled with antiseptic solution, thus ensuring that the urethra is subsequently flushed with a cleansing substance.

Cases of retention of urine due to stricture used to reach the Mayo Hospital after a number of ineffectual attempts had been made outside to relieve the condition. If such a case is at all toxic I have found that it is advisable to institute continuous drainage of the bladder, inserting, by means of a trocar and cannula, a de Pezzer self-retaining suprapubic catheter. The self-retaining catheter is left in position until all signs of toxaemia have disappeared and until the stricture has been dilated to size 8/11 English gauge or until the patient begins to pass urine naturally, which he usually does.—I am, etc.,

F. R. W. K. ALLEN.

Injectable Liver Extracts

SIR,—Dr. H. W. Fullerton (Feb. 10, p. 197) refers to his experience of liver extracts possessing little or no potency, and states that the establishment of an official unit of activity would bring to an end the marketing of such extracts. He broadens the issue raised in our recent article (Jan. 20, p. 75) by suggesting that one method of standardization be adopted internationally. While we agree that the adoption of different standards in different countries would be unfortunate, the failure to adopt any standard at all would in our view be even more unfortunate.

In our paper we defined a unit of activity based on the more usual method of clinical testing in this country, which depended on the response obtained over the first fortnight of therapy. This period of therapy is approximately the same as that used in the *U.S.P.* method of assessing activity. We would expect that appropriate comparative tests would show the two units to be approximately equivalent, but we feel that the injection of the whole test dose at the commencement of therapy bears a much closer relationship to actual clinical practice than does injection of smaller doses at more frequent intervals. While it would seem convenient to express the potencies of liver extracts in terms of units, such as we have defined, we feel it is desirable at least that such agreement should be reached as will permit the potency of every batch of every liver extract on the market to be expressed in terms that allow of clear comparison. This requires general agreement as to conditions of test and criteria of satisfactory response. If this can be achieved it will provide a very important measure of protection to both the doctor and the patient against both inactive extracts and misleading statements by manufacturers.—We are, etc.,

W. B. EMERY,
W. J. HURRAN.
Greenford, Middlesex.

Civilian Respirator as Anaesthetic Mask

SIR,—With reference to the comments of Dr. Margaret Joad (Feb. 10, p. 199) and Drs. F. G. Etheridge and F. M. Sandford (Feb. 17, p. 234) on the civilian respirator anaesthetic mask, I should have stated that the mask would not support without some sagging the heavy double tubing of the latest anaesthetic apparatus. For the time being I have been content to anchor this double tubing to the pillow, and use the shortest possible single lead to the face-piece. The resulting increase of dead space is unfortunate, but I cannot admit to any visible evidence of a CO_2 "build up," and the mask most certainly does not leak.

However, I agree the expiratory valve is too distant and should, and of course easily could, be put in its proper place at the junction of tube and face-piece. After induction, anaesthesia has been maintained in a closed circuit.—I am, etc.,

Bedford. F. S. VAUGHAN.

Barotrauma

SIR,—In the annotation on barotrauma (Feb. 10, p. 190) the work of Armstrong and Heim is described as "the foundation of accurate knowledge of the physiology of the Eustachian tube in aviation, though the work was published only seven years ago." The pioneer work was done more than twenty years ago by Sydney Scott, whose outstanding paper, "The Ear in Relation to Certain Disabilities in Flying," was published in the Special Report Series of the Medical Research Committee, No. 37, Reports of the Air Medical Investigation Committee, VIII and IX, in 1919.

Some honour is due to the prophet, even in his own country. —I am, etc.,

London, W.1. F. W. WATKYN-THOMAS.

Deaf Aids

SIR,—I have read with interest the letters from Mrs. E. M. Barlow (Jan. 27, p. 130) and Mr. E. T. Jordan (Feb. 17, p. 237). I can sympathize with Mrs. Barlow. I, too, have been deaf many years and use a deaf aid without which I should be entirely lost. I keep three aids, but recently two have had valve failures. In the older one, the valves, H.11 and L.11, are, I believe, not now procurable, and I was on the point of getting my suppliers to alter it to a later type. Ten days ago, however, my second aid had a valve failure, and the firm tells me that they can do nothing because they cannot get the valves (in this case a 2-volt Hivac).

I have no fault to find with the firm. Their instruments and servicing are excellent, although there is an inordinate delay in getting things done—e.g., seven to ten days to replace a cord, the work of perhaps five minutes. They say that the position with regard to valves has been difficult for the past twelve months and that now they haven't a single value left. This, too, in spite of urgent representation to the Board of Trade. I have written to the Secretary of the B.M.A. asking him if the Association could make urgent representation to the President of the Board of Trade. After all, the social handicap of deafness is quite difficult enough without having added to it the prospect of being unable to carry out one's duties.—I am. etc.,

Fareham. ERNEST SHAND.

Mag. Sulph. for Infantile Gastro-enteritis

SIR,—The article on infantile diarrhoea and vomiting by Drs. M. B. Alexander and Y. Eiser (Sept. 30, 1944, p. 425) and the leading article on infantile gastro-enteritis (p. 439) traverse a most important subject in a comprehensive and interesting manner.

For the sake of completeness the treatment of this disease by fractional doses of magnesium sulphate may be helpful. When I was on the honorary staff of the Johannesburg Hospital during the last war I was at one time in charge of all the children's wards before the establishment of a separate children's hospital, so that ample opportunity was afforded for watching the results of treatment. The mag. sulph. treatment of infantile gastro-enteritis was first instituted in Johannesburg by the late Dr. E. P. Bauman, who was held in high esteem as a children's specialist. I obtained such good results with this treatment that it was introduced into all my wards as a routine procedure in all cases of infantile gastro-enteritis.

The principle of the treatment is the administration of fractional doses of, say, 2 to 5 grains of magnesium sulphate every one, two, or four hours, according to the age and condition of the patient. It was recognized that, whereas in large doses mag. sulph. was aperient in its action, in very small doses it acts as an astringent. When necessary, other better-known treatments were combined with the giving of mag. sulph.—such as a preliminary dose of ol. ricini, the withholding of food and giving of much plain water, together with saline transfusion when required. Intestinal lavage in severe cases was also helpful, but the small patients were never left to pass the enema themselves; it was siphoned off by the rubber tube kept in the rectum, so saving the strain and tenesmus that often accompany the voiding of an enema.

The results were almost universally successful, except in cases that were too advanced when admitted to hospital. Mild cases that were treated as out-patients were also, as a rule, very satisfactory in the results.—I am, etc.,

Durban, S.A. L. ERASMUS ELLIS.

Erythrocyte Sedimentation Rate in Infective Hepatitis

SIR,—In his article on "The Erythrocyte Sedimentation Rate in Infective Hepatitis and in Malaria" (Jan. 6, p. 9) Lieut.-Col. P. Wood states that about 85% of cases of infective hepatitis have an E.S.R. below 10 mm. p.h. in the first 10 days. Our experience confirms his findings. Sporadic readings in 31 cases in the first 12 days had a range of 2-8 mm. p.h. The mean value was 3.87, the standard deviation 1.916, and the coefficient of variability 47.9. Readings in 63 cases between the 13th and 30th days had a range of 3–29 mm. p.h. The mean value was 10, the standard deviation 5.89, and the coefficient of variability 58.9. Several readings in 8 cases gave the following results:

1. 7th day–6 mm. p.h.; 13th day–13 mm.
2. 11th day–2 mm. p.h.; 17th day–7 mm.
3. 10th day–5 mm. p.h.; 18th day–8 mm.
4. 10th day–2 mm. p.h.; 17th day–18 mm.
5. 10th day–4 mm. p.h.; 20th day–16 mm.; 30th day–10 mm.
6. 11th day–6 mm. p.h.; 21st day–14 mm.; 30th day–10 mm.
7. 9th day–7 mm. p.h.; 14th day–29 mm.; 17th day–25 mm.; 28th day–16 mm
8. 12th day–4 mm. p.h.; 16th day–9 mm.; 30th day–5 mm.

—I am, etc.,

P. ROBINSON,
Central Mediterranean Force. Capt., R.A.M.C

Artificial Insemination

SIR,—Having seen the name of this College referred to i correspondence on the above subject, I write to inform you an your readers that this matter has been discussed by the Counci of this College and will be further discussed at the next meeting. After that the Council hopes to publish its views.—I am etc.,

Royal College of Obstetricians
and Gynaecologists.
W. GILLIATT,
Deputy Honorary Secretary

SIR,—In his letter (Feb. 17, p. 236) Sir Charles Gordon Watson uses these words: ". . . pseudo-adulterous practice and that these result in illegitimate babies for all time." Sir Charles is not the first, nor do I suppose he will be the las to fall into such error. Apparently it cannot be contradicte too frequently. The babies to which he refers would be bor in wedlock and would therefore be legal in every sense of th word.—I am, etc.,

Herne Hill, S.E.24. KENNETH MCFADYEAN.

SIR,—The letter of Dr. M. G. Eggleton (Feb. 17) calls fo some comment. She refers to "emotional reaction," and t the "narrow-minded puritanism, or bigoted catholicism" c some of the correspondents. May I suggest that in an age i which so many moral standards are obscure, and everyon tends to become his or her own infallible authority on ethic it is not surprising she should ascribe to others the sam confused state of mind she herself enjoys. Ethics is but th science of conduct, and as such is not founded on emotio but on knowledge—the knowledge of man's duty to his fello man. It is unfortunate for the modern age that ethics is o of the few sciences in which there is no progress; what w wrong a thousand years ago is still wrong to-day, and alwa will be, at least for those who believe that this world has purpose, and whose philosophy of life is not that of pragmat humanism.—I am, etc.,

Felton, Northumberland. E. A. WELSH.

Final M.B. of London University

SIR,—We hear daily over the wireless of the sympathy a help that are going to be extended to all ex-Servicemen. It is pity that the University of London does not feel the sa sentiments, and is by its new regulation deliberately plac them at a disadvantage as compared with their more fortun successors.

The regulation in question announced that candidates in t Final M.B. will be credited with the subjects in Part III in whi they pass and re-examination in these subjects will be excus

On further inquiry I find that this only applies to those who have been students throughout the war years and are now beginning to sit their finals, and not to those who may have passed in these subjects early on in the war, spent most of the war in the Services, and now wish to finish off their degree.

I should be most grateful if you would kindly give this letter some of your valuable space, as perhaps it will encourage others, with more pull than I, to do what they can to alter this lunatic state of affairs.—I am, etc.,

D. S. PORTER.

The Young Married Doctor

SIR,—To the correspondence on the young married doctor may I add some lines based on experience as a full-time State servant with the Ministry of Pensions, which may give some pointers to what may be expected under a State hospital service.

First it should be realized that the convenience to a hospital in having its medical staff on the premises is very real, to such an extent that the staff is in danger of exploitation on that account. No doctor can be expected to mortgage his whole life to a hospital, but, in fact, that is what often happens. Although the nursing staff are usually resident they are not expected to be on call the whole 24 hours, and there seems no reason why a charter of conditions cannot be negotiated for hospital officers not less favourable than those given to the nursing staff under the Rushcliffe report, the domestic staff under the Hetherington report, and, last but not least, those enjoyed by shop assistants under the Shops Acts.

As regards accommodation for married doctors, I consider rooms in the hospital building most unsuitable for normal married life for reasons which are obvious (cooking, privacy, family, etc.). The best solution is for the governing bodies to buy or erect houses in the immediate vicinity of the hospital, each self-contained and connected by telephone to the hospital. These could be let at a low rent to such of the staff (medical or executive) who desired them. In letting such houses priority would be given to the medical staff, in that they would be permitted to do any emergency call duty if they occupied such houses adjacent to the hospital. With this is bound up the question of emergency duty. One person does duty in turn in a Ministry hospital for 24 hours, sleeping in during that time. This is light where there are seven or more medical officers, but it is no joke when there are only two or three, for it cuts everely into nearly every week-end, since it is not permissible to eave the premises for a moment. Yet for this service medical officers get no more leave than the clerical staff, who work only rom Monday morning to Saturday midday, and enjoy all the ustomary public holidays.

Provided such houses are situated as described the medical officers could well do their emergency duty at home, on the lear understanding that they will be available on their allotted nights. In practice this might mean that contact was more quickly and easily made with the M.O., for the difficulty someimes of finding a person in the hospital premises is well known. Yet officialdom is stubborn and insists that medical officers leep in; in one case permission was refused a man to be on uty (on the telephone) at his home, which is separated from the ospital by a field. Conversely, *where it is insisted that M.O.s* keep in during their emergency duty there should be no restricons requiring them to live within a certain distance of the ospital.

As regards hospital pay the Ministry has scales comparing avourably with other employing authorities, but even so there hould be a minimum of £500 p.a. after qualification. We hear lot about proposed reforms after the war, but surely the time now, when all commodities are so expensive. Is no consideraon to be given to the years of unremunerative labour, and es, to fit one for the task? There is also the principle of equal pay for equal work" to be considered. Nobody would eny that an experienced employee is of much more value than raw recruit, but to strike the balance afterwards is more fficult. Value is not in direct proportion to age. Yet even e present Joint Industrial Councils have correlated employees' ages with age. All this is going on now, and the Governent is understood to desire fixed minimum wages in the rious industries to be settled before the end of the war. The me, therefore, for considering hospital pay is only too ripe.

Finally I might add that personal files are kept at headquarters for each medical officer, in which all the correspondence regarding him is preserved. Because of this certain small concessions or criticisms may not be made as the M.O. concerned does not wish the item to be "spotted" when his promotion is under consideration.—I am, etc.,

"TEMPORARY CIVIL SERVANT."

A Faculty of Ophthalmologists

SIR,—The announcement of the formation of the Faculty of Ophthalmologists (Feb. 3, p. 160) appears to me to come at an inopportune time. To increase the number of organizations to watch over ophthalmologists' interests is to invite division of effort and confusion of thought.

I do not like the Faculty's proposal to have two kinds of members. We want to encourage the younger men, and the suggestion that only six members of council are to be elected by the associate members—that is, those of two to five years' standing, and others of more seniority, who are not on the staff of a hospital of arbitrary size—while the older members elect 15 is undesirable. How can the Faculty be fully representative if it excludes the part-time ophthalmologist, whose numbers are, indeed, far higher than those of the full-time practitioner? It is from these "part-timers" that we must expect much help in the proposed National Health Service, for without them we shall be unable to put forward a scheme for a medical examination for every patient, for which the Government has expressed a desire.

"United we stand, divided we fall." The Ophthalmic Group of the B.M.A. is surely best constituted to be the guardian angel. It is democratically elected, and all electors are of equal status, whether practising ophthalmology wholly or predominantly, and is, therefore, fully representative. Let all ophthalmologists rally round the B.M.A., attend the regional meetings, and put their views and desires before their representative on the Ophthalmic Group Committee. By so doing we present a united front to the Minister of Health when the time comes.—I am, etc.,

Edinburgh. C. R. DUNCAN LEEDS.

Cecil Joll Memorial Fund

SIR,—We, colleagues and friends of the late Cecil Joll, feel that some recognition of his distinction in the science and practice of surgery should be put on permanent record. This, we suggest, might take the form of an annual lecture or prize essay sponsored by the Royal College of Surgeons of England, as shall be determined by the President and the Council, of which Cecil Joll was an active member. Contributions from all those in sympathy with this object should be sent to: The Manager, National Provincial Bank, Marylebone High Street, London, W.1, marked "Cecil Joll Memorial Fund."—We are, etc.,

ELIZABETH BOLTON JENNER HOSKIN
DANIEL T. DAVIES CEDRIC LANE-ROBERTS
HORDER LIONEL E. C. NORBURY

The Services

The following appointments and mentions have been announced in recognition of gallant and distinguished services in the field:

C.B. (Military Division).—Major-Gen. W. C. Hartgill, O.B.E., M.C., late R.A.M.C.

O.B.E. (Military Division).—Major (Temp. Lieut.-Col.) B. W. Rycroft, R.A.M.C.

M.B.E. (Military Division).—Capt. T. B. McMurray, R.A.M.C.

Mentioned in Dispatches.—Brig. (Temp.) R. A. Hepple, O.B.E., M.C., late R.A.M.C.; Cols. (Temp.) T. Menzies, O.B.E., and T. Young; Lieut.-Col. (Temp.) J. P. Parkinson; Lieut.-Col. (Acting) D. L. Owen; Majors (Temp.) L. S. Rogers, M.B.E., and O. S. Williams; Capts. D. Collins and J. R. Rickett, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Died.—Capt. Basil Reid Caygill, R.A.M.C.

Died on active service in Australia.—Surg. Lieut. Malcolm Joseph Clow, R.N.V.R., who was awarded the Albert Medal in gold in 1943 for his gallantry in saving others when H.M.S. *Ibis* was left sinking after an air attack off North Africa.

Obituary

F. W. EURICH, M.D.

Emeritus Professor F. W. Eurich, famous for his work on anthrax in Bradford, died at Dibden Purlieu, near Southampton, on Feb. 16. He held the chair of forensic medicine in the University of Leeds for over 24 years, was consulting physician and consulting pathologist to the Bradford Royal Infirmary, and had been specialist medical referee to the Home Office for anthrax, and aniline and lead poisoning.

Frederick William Eurich, son of Richard Eurich, was born in 1867, and studied medicine at the University of Edinburgh, graduating M.B., C.M. with honours in 1891, and won the gold medal for his M.D. thesis in 1897 after postgraduate work at Heidelberg, Frankfort, Berlin, and elsewhere. Having served as assistant medical officer and pathologist to the Lancashire County Asylum at Whittingham he became bacteriologist to the City of Bradford and to the Bradford Anthrax Investigation Board, and worked for many years on the visiting staff of the Royal Infirmary and the Royal Eye and Ear Hospital. The Anthrax Board had been set up by the Home Office in conjunction with the Bradford Chamber of Commerce, and Dr. Eurich was appointed to carry out investigations, not without considerable danger to himself, on the various wools and hairs, and in the end he found a method of killing the bacillus in any sample without detriment either to the material or to the worker. Forty years ago the whole Bradford district was vitally concerned in the menace to its workers from wool-sorters' disease, and Dr. Eurich, by disclosing sound preventive measures and by introducing improved treatment of the disease when contracted, brought about effective reduction in incidence and fatality. When he retired in 1937 a public presentation was made to him at a farewell dinner held in the Midland Hotel, Bradford, and a few weeks later he received in Manchester the medal of the Textile Institute for his research into anthrax; on each occasion many tributes to him were paid by representatives of the wool trade. He was the author of papers on diagnosis, treatment, and control of industrial anthrax published in the *Lancet* and the *British Medical Journal,* and contributed the chapter on anthrax to the Medical Research Council's encyclopaedic *System of Bacteriology* published in 1930. A member of the B.M.A. since 1897 until he retired a few years ago on account of failing sight, he served as vice-president of the Section of State Medicine and Medical Jurisprudence at the Annual Meeting at Aberdeen in 1914, and vice-president of the Section of Medicine at the Bradford Meeting in 1924. Both the Bradford and the Leeds and West Riding Medico-Chirurgical Societies made him an honorary member.

J. B. D. writes:

The death of Dr. Eurich caused great regret in Bradford. Though he had retired from practice eight years ago, his works still remained fresh in the memory of his colleagues and the public at large, and none had been a more notable citizen when resident in their midst. The son of a German merchant who settled in Bradford, he was born in Saxony, but brought when a few months old to England. He received his early education at the Bradford Grammar School in the time of Dr. Keeling. Thence he went to Edinburgh. In Bradford he was appointed assistant physician to the Royal Infirmary in 1899, and succeeded Dr. R. H. Crowley as full physician in 1907. On his retirement from the acting staff in 1927 he became consulting physician. He was elected to the chair of forensic medicine at the University of Leeds in 1908, retiring therefrom in 1932, with the title of Professor Emeritus.

Eurich's earlier fame was founded on his activities as bacteriologist to the Anthrax Investigation Board, set up in 1905. His work for this committee was long and arduous, examining specimens of wool and hair and making thousands of cultures. Within a few years there was a considerable decline in the number of deaths, and eventually a Government disinfection station at Liverpool was established, enabling imported wool to be disinfected before reaching the workers. The disease is now rare in the district. As a physician his services were in great request over a wide area, and his opinion on a case was much valued. He worked with tireless energy. With a good general knowledge, both clinically and by incessant reading, of medicine, his forte was neurology. Therein he was an expert. He was in his element in solving the problem presented by an obscure nerve case, and never rested till he had made a diagnosis, almost invariably correct. A member of the Society of Friends, his chief characteristic was his altruism: he would cheerfully spend hours on cases in which there was no scintilla of fee or reward, and after his retirement from the full staff held a weekly clinic at his rooms for patients too poor to pay his fee. Much interested in delinquency, he performed valuable service by his examination of delinquents referred to him by Dr. Coddington, the learned stipendiary magistrate for Bradford. The latter in a tribute said, "He was a pioneer in the application of medical and psychological knowledge to the question of delinquency as opposed to psychiatry, which by itself is not so powerful an instrument for good." On his retirement from active practice he was entertained to dinner by the medical men of the district and the Textile Trade Societies, who severally made him presentations. He was also awarded the Textile Institute's Gold Medal, a rare honour for one not actively engaged in the trade. He leaves a widow and five children, the elder son being Richard Eurich, the well-known artist. His memorial will be his ungrudging labours for his fellow-men.

ASTLEY V. CLARKE, M.D.

We regret to announce the death on Feb. 21 of Dr. Astley V. Clarke, who had been for many years a leading figure in Leicestershire and Rutland, and took an active part in the work of the British Medical Association, both locally and at headquarters.

Astley Vavasour Clarke, son of Julius St. T. Clarke, M.S., F.R.C.S., was born at Leicester on Feb. 7, 1870, and from Oakham School entered Caius College, Cambridge, where he took his B.A. in the Natural Sciences Tripos of 1892. He went to Guy's Hospital for his clinical course and graduated M.B., B.Ch. in 1895, proceeding M.D. three years later. After a year as house-physician at Guy's and some postgraduate study abroad he began practice in his native town and was elected to the visiting staff of the Leicester Royal Infirmary, becoming eventually honorary consulting physician and consulting radiologist. The outbreak of war in August, 1914, found him already a lieut.-colonel in the R.A.M.C. (T.F.), and he served as A.D.M.S. to the North Midland Division and afterwards administrator of the 5th Northern General Hospital, Leicester, with the rank of colonel, A.M.S. After the war he became honorary consulting physician for the East Midland Region or behalf of the Ministry of Pensions, and for four years was medical director of the Frith Home of Recovery for neurasthenia cases under that Ministry.

Dr. Astley Clarke's record of public service in the City an County of Leicester is most impressive. He was a Deput Lieutenant of the County and an alderman and Justice of th Peace for the City; he also helped largely to found Universit College, Leicester, and was a vice-president and the chairman o its council. He had served as a member of the City Counc and as chairman of its Health Committee, as president of th Literary and Philosophical Society, and as chairman of th City General Hospital. He was County Controller of th Leicester V.A.D., a member of the Leicester and Rutlan Territorial Association since 1910, and had been High Sheri of Rutland. One of the moving spirits of the Leicester Publi Medical Service, he acted as honorary treasurer from it inception in 1912, and in recognition of this was presente with his portrait in oils at the close of 1938. Particularly i the early and difficult stages of the formation of the firs Public Medical Service in the country his untiring work an his advice were of inestimable value to the local professio and also to the community. He had been chairman of the loc Division of the B.M.A. and president of the Leicester Medic Society.

Dr. Astley Clarke joined the B.M.A. in 1897 and first repr sented his Division at the Swansea Meeting in 1903; he w honorary Local General Secretary for the Leicester Meetin two years later and served for a period on the Central Counc He held office as vice-president of a Section at three Annu Meetings: Haematology and Vaccine Therapy (1909), Electr therapeutics and Radiology (1911), Medicine (1926). At hea quarters he served on the Hospitals Committee continuous from 1920 to 1929, and for three years on the Private Practi Committee; he was also a member of the General Medic Service Scheme Committee, and of a number of subcommittee iore particularly the Public Medical Services Subcommittee, n which his experience at Leicester gave great weight to his pinion.

His main recreation in the by-hours of an arduous and many-sided working life was the discovery of village antiquities, and e had one of the finest collections of them in the country, ncluding agricultural and household implements. He wrote a hort history of Lyddington, the Rutland village where he had is country house.

H. MASON LEETE, M.D., B.Hy., D.P.H.

r. Harold Mason Leete, medical superintendent of the Hull ity Hospital, the Tuberculosis Sanatorium, and the Evan raser Hospital, died after a brief illness on Feb. 15 at e age of 50. Educated at St. Bees School, he went to tudy medicine at the University of Durham College of ledicine, Newcastle-upon-Tyne, qualifying M.B., Ch.B., and I.R.C.S., L.R.C.P., in 1917. Having chosen public health as is specialty he obtained the D.P.H., became a Bachelor of lygiene of the University of Durham in the following year, nd in 1921 proceeded to the M.D. After serving as house-physician and house-surgeon at the Royal Victoria Infirmary, ewcastle, he went to the Edinburgh City Sanatorium as esident medical officer in charge and ten months later was ppointed senior medical assistant and bacteriologist at the dinburgh City Hospital for Infectious Diseases. In 1920 e joined the staff of the M.O.H. of Birkenhead and was rimarily engaged on tuberculosis, infectious diseases, and acteriological work. His interest in the diagnosis and treatment of cases of infectious disease deepened with the passage f the years, and his contributions to literature on bacteriological technique and clinical findings were always carefully repared and concisely expressed. While at Edinburgh he id research on the Schick test in diphtheria and published e first English paper on the subject in the *Lancet* of an. 24, 1920. In 1924 he published a paper jointly on an utbreak of typhus fever in England.

Since coming to Hull in 1930 (writes N. G.) he engaged on valuble research work upon gravis diphtheria, and has materially added o our knowledge of this important subject. An expert clinician, a killed bacteriologist, and an able administrator, Dr. Leete has proved imself to be an admirable medical superintendent. Beloved by his atients, especially by the children, he was held in high regard by is professional colleagues, who invariably attended his clinical emonstrations in large numbers. The loss of his son while serving ith the R.A.F. in North Africa was a serious blow to him. We, is colleagues in the Public Health Department and on the hospital affs, mourn the loss of a dear friend and the medical profession a istinguished graduate. Dr. Leete was at the time of his death a ember of the council of the East Yorkshire Branch of the British ledical Association and of the council of the Hull Medical Society. incere sympathy is extended to his widow and daughter.

FREDERIC HERBERT STURDEE, F.R.C.S.Ed., died at his home Little Walsingham, Norfolk, on Feb. 2. He received his edical education at St. Thomas's Hospital and qualified I.R.C.S., L.R.C.P. in 1896. He subsequently held appointments as fourth medical officer at the Sussex County Hospital, ssistant medical officer at the Chelsea Infirmary, and senior ouse-surgeon at the Great Northern Hospital. He obtained e F.R.C.S.Ed. in 1901. He started in general practice the me year at Little Walsingham and for 44 years served evotedly and with unusual skill a large part of this rural rea. His only passion in life was surgery, and he was a aster of the art. He played a great part in the foundation f Wells Cottage Hospital in 1910, and from its foundation as honorary surgeon. He was a skilled operator, and very any people owe their lives to his skill alone. He dedicated is life to the service of others and to surgery, and if ill-health early manhood had not prevented it he would have made a reat name in a wider field. He was a great man in the best ense of the term, and everyone who knew him loved him. le died, as he would have wished, in harness. He had been a ember of the B.M.A. for over forty years.—E. W. H.

Dr. **HENRY FRANK CURL**, who practised for many years at Vokingham, Berks, and was mayor of the borough ten years go, died suddenly at Overstrand, Norfolk, on Feb. 10. He egan the study of medicine at Cambridge, and after taking his B.A. degree went on to the London Hospital, qualifying M.R.C.S., L.R.C.P. in 1906. He held successive appointments as house-physician and house-surgeon both at the Poplar Hospital and at the Prince of Wales's Hospital, Tottenham, and joined the B.M.A. in 1909. At Wokingham Dr. Curl was medical officer to the Fire Brigade, to the Lucas Hospital, and to the Cinematograph Trade Benevolent Fund Convalescent Home; he was also physician to the Royal Merchant Seamen's Orphanage at Bearwood.

Dr. **FRANCIS DUDLEY** died suddenly at his home in Newton Abbot, Devon, on Feb. 13. He had suffered from recurring anginal attacks and from a painful arthritis of the hip-joint for the past year, but was apparently improving, and the news of his passing came as a shock to his many friends. He was born on Aug. 9, 1873, in the town of Tipperary, Ireland, where his father, the late Henry Dudley, M.D., practised, and was educated at Christ's Hospital, London, and at Horsham. He proceeded to the medical school of Trinity College, Dublin, and qualified as L.R.C.P.&S.I. and L.M. Rotunda in 1896. After assisting his father for a short time he came to England as A.M.O. at the Lancashire County Mental Hospital, Whittingham, and then, in 1897, to a similar post at the Cornwall County Mental Hospital, Bodmin, where he spent the rest of his active professional life, being appointed medical superintendent of that large institution in 1914. He retired in 1931 after 34 years' service, and then went for several voyages as ship surgeon. On his return he settled with his family in Newton Abbot, and at the outbreak of the present war joined the Home Guard as a private and dispatch rider, and later acted as M.O. to the battalion. He was a member of the B.M.A. and of the Royal Medico-Psychological Association from whose meetings he was seldom absent. Dr. Dudley was a man of powerful physique, and in his youth a fine athlete and an expert swimmer and diver. He had a passionate love of the sea, and some of his happiest days and nights were spent with the Cornish fishermen. He had an inexhaustible store of tales and ballads of his native land and of his adopted county of Cornwall, and was an excellent raconteur. His open, handsome face, with those kindly eyes and humorous mouth, and the air of optimism and happiness which radiated from him, made him a welcome guest everywhere, and will never be forgotten by his host of friends. The most generous and unselfish of men, tolerant, kindly, and understanding, with a perfect genius for friendship, he was the ideal medical superintendent, and his patients adored him. No man of my acquaintance better fulfilled the Masonic "grand design of being happy and communicating happiness." *Atque in perpetuum, frater, ave atque vale.* Dr. Dudley married Miss Josephine Pomeroy of Bodmin, and she and their daughter survive him. All his old friends will sympathize with them in their irreparable loss.—W. S.

The death of Dr. **JOHN DOUGLAS HOPE FRESHWATER** at the age of 68 took place recently at Worthing. On leaving Cambridge, where he graduated as B.A. in 1899, he did his clinical years at St. George's Hospital and qualified as M.B., B.Ch. of his University in 1903, and M.D. in 1912. Postgraduate study in dermatology and syphilology at Berlin, Paris, and Aix-la-Chapelle filled in a few years; later he became M.R.C.P. and returned to St. George's as physician to the skin department and director of the V.D. clinic. He was also appointed dermatologist to the L.C.C. and physician to the Western Skin Hospital. He was among quite the earliest dermatologists to realize the value, indeed the necessity, of an *x*-ray installation in the treatment of various skin complaints; and this prescience brought him, deservedly, a reputation both among his colleagues and among the public at large. On retirement from St. George's, where he had been lecturer in dermatology in the medical school, he became consulting physician for diseases of the skin to the hospital. Though of strongly built frame, Freshwater was not constitutionally a strong man.

Dr. W. Radcliffe (Wivenhoe, Essex) writes: Your obituary notice of Dr. T. **HARRISON BUTLER** omits to mention one of his most remarkable accomplishments, for he was without doubt the leading amateur designer of small yachts in the country. His name became a hall-mark which has made little ships from his board much sought after around our coasts and abroad. He was a master draughtsman, and an experienced shipbuilder said to me that one of his designs was the most beautiful drawing he had seen. He also led the way in the more theoretical side of boat design, and his great experience was such that the editors of the yachting press called upon his services as a judge and critic of other designers' work, and he was always ready and anxious to encourage others in the hobby he had so much enjoyed himself.

Dr. P. Catherine Evans writes: Many surgical tributes by eminent members of the profession have been paid to the late Mr. Cecil A. Joll. But may I, an old student and a most grateful ex-patient, write a few words of appreciation on behalf of that vast number of thyrotoxic patients who owe so much to him and his staff for a return to normal health and strength. Those who have not suffered from thyrotoxicosis may not realize the mental as well as physical stresses and strains which have to be borne by the patient. Cecil Joll had that great gift of inspiring complete confidence, trust, and optimism in his patients, and this gift, combined with his superb surgical skill, made him the ideal surgeon for such cases. We are indeed grateful to him for his life's work and we deeply regret his untimely end.

The following well-known medical men have died abroad: Dr. Benjamin Franklin, instructor in surgery at the University School of Medicine, Philadelphia, aged 53, of acute lymphatic leukaemia; Dr. Ovidio Meira, one of the leading orthopaedic surgeons of Rio de Janeiro, aged 64.

Medical Notes in Parliament

Tuberculosis among Returned Prisoners-of-War

On Feb. 20 Mr. Hogg asked the Secretary of State for War what special steps had been taken to diagnose and treat cases of tuberculosis among returned prisoners-of-war. Sir James Grigg: All returned prisoners-of-war are given a careful general medical examination as soon as possible after their return to this country. In cases in which there is the slightest reason to suspect the presence of tuberculosis they are referred for specialist examination, and, if necessary, for appropriate treatment in military hospitals and certain E.M.S. hospitals until such time as they can be transferred to civil sanatoria, with which the Minister of Health is concerned.

Mr. Hogg asked if, having regard to the increased danger of tuberculosis among prisoners-of-war, it would be practicable to arrange for them to have an x-ray examination when they came back to this country. Sir James Grigg said that the Government was considering what further steps it could take. He was not sure whether sufficient equipment and medical skill were available now to test all the men, but the Government was asking the Germans, through the Protecting Power, to give us a list of the latest date on which our prisoners were examined by x rays in Germany. That might help in getting a further line on the medical condition of these men.

Dr. Summerskill asked whether, as the Minister of Health had said there were 4,000 tuberculous persons awaiting admission to sanatoria, Sir James Grigg could assure the House that no returned prisoner-of-war or ex-Serviceman was among the 4,000. Sir James Grigg said he did not notice the answer, but he had been in communication with the Minister of Health about the admission, as a temporary measure, of some of these tuberculous cases to E.M.S. hospitals.

Salaries of African M.O.s

Mr. Riley on Feb. 14 asked what opportunities there were for native African assistant medical officers to qualify as full medical officers, and whether an initial salary of £96 per annum was adequate for a man who had studied medicine for a number of years and qualified as a doctor. Col. Stanley said the building up of medical schools in Colonial Territories was a matter to which he attached great importance and on which the Asquith and Elliot Commissions would no doubt make recommendations. He was consulting the East African Governments as to the salaries of these assistant medical officers. The Government had already considered the subject.

Drug and Lunacy Administration in Northern Ireland

Miss Ellen Wilkinson moved on Feb. 16 the second reading of the Northern Ireland (Miscellaneous Provisions) Bill. She said that, under the Therapeutic Substances Act, 1935, therapeutic substances must not be imported into Northern Ireland unless the Ministry of Home Affairs was satisfied that they conformed to the required standard. The Bill contained a clause which would enable the Governor of Northern Ireland, with the consent of the Secretary of State, to transfer these functions to the Ministry of Health and Local Government. Another clause of the Bill provided for the winding up of the Lunacy Fund, which had been established to defray the expenses of the Lunacy Office in Ireland. It was made up of percentages charged on lunatics' estates and certain other fees. In England expenses of lunacy administration were borne by the Exchequer. The clause provided for the same practice to be followed in Northern Ireland.

The Bill was read a second time.

Notes in Brief

Sir Walter Womersley, in reply to Mr. Messer on Feb. 15, said standardized tests were conducted by aural specialists at each Ministry of Pensions Regional Office to determine the most suitable type of aid-to-hearing appliance for deaf ex-Service and civi pensioners. In addition to the one at Manchester University, there were special clinics at certain of the London hospitals, which were consulted in individual cases of difficulty.

A case reported as smallpox in Anglesey was in a serving soldier in a military camp. The Army medical authorities found that it was not a case of smallpox.

The latest returns show the number of beds provided by local authorities in England and Wales for tuberculosis as approximately 29,000, and the number of patients on waiting lists for institutiona treatment as approximately 4,500. The major difficulty, Mr. Willink says, is staff.

The Nurses Act received the Royal Assent on Feb. 15.

The Family Allowances Bill was introduced on Feb. 14 and has been printed.

Discharged soldiers in civilian life can claim National Health Insurance benefit for sickness that could be attributed to malaria suffered during their military service, subject to the normal statutory conditions for title to benefit being satisfied.

Medical News

A meeting of the Medical Society of the L.C.C. Service will be held at St. Stephen's Hospital, Fulham Road, S.W., on Thursday, March 8, at 2.30 p.m., when members of the staffs of St. Stephen's and St. Mary Abbots Hospitals will demonstrate cases.

The Royal College of Nursing has arranged a conference on "The Nurses' Responsibility in the Control of Venereal Disease" to be held at the College, Henrietta Place, W., on Thursday, March 15 at 6 p.m.

A meeting of the Pathological Society of Great Britain and Ireland will be held in London, at St. Thomas's Hospital Medical School on Friday, March 23, and Saturday, March 24.

The Ophthalmological Society of the United Kingdom proposes to hold its annual congress in London on Friday and Saturday, April 13 and 14, at the Royal Society of Medicine. There are two subjects for discussion: the first, at the Friday morning session, is "The Ocular Sequelae of Head Injuries"; the second, at the Saturday morning session, is "Plastic Repair of the Lids." Part of the Friday afternoon session will be devoted to a joint clinical meeting with the Ophthalmological Section of the R.S.M. On account of the difficulty in obtaining hotel accommodation in London, those who require it should make their arrangements in good time.

For the benefit of teachers, societies, and others, the British Medical Students' Association (B.M.A. House, Tavistock Square, W.C.1) has published, with the help of numerous other organizations, a catalogue listing almost all the available documentary films on medical subjects, with details of cost of hire, running time, and size and the names of the distributors of the films. The price of thi guide is 1s.

A sum of £1,657 has been subscribed by the A.R.P. Wardens o London districts A to D, and on Feb. 10, in the Tudor Room of Zeeta's Restaurant, Putney, a cheque for this amount was handed to Mr. J. R. Lancaster, chairman of Putney Hospital, to endow a bed in memory of 14 of their comrades killed by enemy action. Mr. Lancaster said that so large a donation, apart from bequests, had never been received by the hospital since its foundation in 1912 with 20 beds. Since that date the building had been much extended, so that in 1943 no fewer than 1,400 patients were treated in the wards. In addition to endowing a bed the Wardens' gif would be sufficient to defray the expense of a short-wave diathermy set.

The Association for the Study of Diseases of the Chest was formed on Jan. 26 at a meeting at Manson House, Portland Place, where there were 53 people present. The Association consists of physicians, surgeons, pathologists, radiologists, anatomists, and physiologist primarily interested in diseases of the chest. The following officer were elected: *President*, Mr. A. Tudor Edwards. *Vice-presidents*, Dr. Geoffrey Marshall and Dr. Roodhouse Gloyne. *Hon. Treasurer*, Prof. Barnard. *Hon. Secretary*, Mr. P. R. Allison. *Editors*, Dr. Clifford Hoyle and Mr. Norman Barrett. *Executive Counci* Mr. William Armstrong, Mr. H. Morriston Davies, Dr. Robert Coope, Mr. R. C. Brock, Dr. J. L. Livingstone, Dr. M. Nosworthy, Mr. G. A. Mason. The objects of the Association are (1) the stud of diseases of the chest and (2) the publication of a journal.

The Queen has consented to the appointment of Princess Margaret s president of the Barnardo Helpers' League in succession to the ite Princess Beatrice. The League was founded in 1892 by r. Barnardo himself to provide a medium by which the young eople of the British Empire might render friendly service to the hildren in Dr. Barnardo's Homes. It has over 2,000 branches and 3,000 members in Great Britain, with many associated groups in lew Zealand, Australia, and other parts of the Empire.

Mr. and Mrs. E. C. Stonehouse have undertaken to give £10,000 o the Clayton Hospital, Wakefield, towards the building of a new hildren's ward in memory of their son, Lieut. Michael Stonehouse, ho was killed while serving his gun during an air raid on Liverpool 1941.

One of several plans now being worked out to improve medical ervices in the West Indies is a scheme to establish a maternity ome in Barbados for the training of midwives. The scheme will e financed by a free grant of £24,000 under the Colonial Development and Welfare Act, 1940.

EPIDEMIOLOGICAL NOTES

Discussion of Table

n *England and Wales* the incidence of measles continued to rise, ,588 more cases being reported than in the previous week. The otal for scarlet fever rose by 65, and for acute pneumonia by 3. There were 52 fewer notifications of dysentery.

The biggest rises in measles notifications were : Yorks West Riding 858, Staffordshire 403, Middlesex 364, Derbyshire 317, Warwickshire 266, Essex 245, and London 241.

Two new outbreaks of dysentery were reported during the week : Cornwall, Wadebridge R.D., 44 cases ; and Suffolk, pswich C.B., 15. London reported 39 cases, Lancashire 31, Middlesex 23, Essex 23, Northumberland 20, Yorks West Riding 19, Buckinghamshire 15, and Cambridgeshire 10.

In *Scotland* rises over last week's totals were recorded as follows : acute primary pneumonia 47, whooping-cough 26, scarlet fever 17, cerebrospinal fever 11, diphtheria 5 ; there were 51 fewer cases of measles. Notifications of cerebrospinal fever were the highest of recent months ; Glasgow reported 18 cases and Edinburgh 10. The incidence of dysentery remained unchanged ; Edinburgh had 27 cases, Glasgow 26, and Stirling 20.

In *Eire* the incidence of diphtheria continued to fall, although the disease is still widespread, the 66 cases appearing in thirty-nine areas. Two outbreaks of dysentery were reported during the week—Waterford C.B. 14 cases, and Waterford, Kilmacthomas R.D. 6.

In *Northern Ireland* scarlet fever notifications fell by 23.

Statistics for Scotland, 1944

The birth rate has risen continuously since 1940, the rate of 19.2 per 1,000 being the highest since 1930. Infant mortality was 65 per 1,000 live births—the same as in 1943, and 8 below the five-years average. Maternal mortality was 3.1 per 1,000 live births—the lowest rate on record, and only half the rate for ten years earlier. The general death rate was 12.9, which is 0.7 below the five-years average. The death rates from all forms of tuberculosis—79 per 100,000—and from respiratory tuberculosis—59 per 100,000—remained at the same level as in 1943. The marriage rate—7.4 per 1,000—was 1.9 below the average for 1939–43, but only 0.2 below the pre-war average, 1934–8.

Statistics for Glasgow, 1944

The birth rate remained high—22.2 per 1,000. The infant mortality rate—95 per 1,000 births—was 13 more than that for 1943, the rise being caused by the autumn outbreak of gastro-enteritis. In 1944 this disease was responsible for 698 deaths of children under 2 years of age, compared with 342 deaths in 1943. Maternal mortality—4.2 per 1,000 births, and the lowest recorded in the city—is about 50% greater than the recent rates for the whole of England and Wales. The general death rate was 13.9 ; for 1942 and 1943 it was 14.0 and 14.1. Deaths from respiratory diseases dropped to 1,312, compared with 1,559 in 1943, and were the lowest ever recorded in Glasgow. Deaths from pulmonary tuberculosis, 1,119, were 67 above the total for 1943 ; the number of registered cases of pulmonary tuberculosis, 2,757, were 21 fewer.

Week Ending February 17

The notifications of infectious diseases in England and Wales during the week included : scarlet fever 1,497, whooping-cough 1,530, diphtheria 427, measles 19,167, acute pneumonia 1,206, cerebrospinal fever 73, dysentery 357, paratyphoid 1, typhoid 11. Deaths from influenza in the great towns numbered 55.

No. 6

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 10.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for : (a) England and Wales (London included). (b) London (administrative county) (c) Scotland. (d) Eire. (e) Northern Ireland

Figures of Births and Deaths, and of Deaths recorded under each infectious disease are for : (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

---

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Yaws and Immunity to Syphilis

Q.—*Does yaws confer partial or complete immunity against syphilis?*

A.—The general consensus is that yaws confers a very substantial, if not a complete, immunity against syphilis.

Incidence of Breast-feeding

Q.—*Is it true that modern women are becoming less able to breast-feed their children? If so, is there are correlation between this and the increasing use of general anaesthesia in labour?*

A.—It depends on what is meant by being "less able" to breast-feed. If it is the inherent ability of modern woman to lactate, an automatic process initiated by an endocrine mechanism and maintained by suckling, which is in question, then surely in this respect she is as well equipped as women in the past—and even better, for her general health is likely to be on a higher level. If modern woman could be divorced from modern conditions of life, there is little doubt that she would nearly always succeed in breast-feeding. Under rural conditions a far higher proportion of women (it has been estimated at 95%) breast-feed their children than do women living in a city.

Although the reason for discontinuing breast-feeding is often recorded as "insufficient milk," suggesting a possible intrinsic deficiency on the part of the breasts, the *primary* causes are often extrinsic, such as: return to domestic work with insufficient help in the home (50%); bad management on the part of nursing and medical attendants; over-anxiety of the mother about her child's progress, with the means for artificial feeding readily available; no desire to breast-feed, mainly for convenience and selfish reasons, etc. During the war an increasing number of women are being confined under the artificial conditions of hospital rather than in the more natural atmosphere of their own homes; the shortage of nurses makes it impossible for them to devote enough time to the individual instruction of the woman during the early days of breast-feeding; the absence from home of the husband, causing anxiety in itself, also leaves the woman with greater domestic responsibilities and worries.

Not all published work supports the contention that there has been a big decline in breast-feeding if the present is compared with the remote past, and a further decline in the last 20 to 30 years. J. C. Spence (*British Medical Journal*, 1938, **2**, 729) concluded that the incidence is declining, but M. Robinson (*Arch. Dis. Childh.*, 1939, **14**, 529) found that among women attending welfare clinics it was approximately the same throughout the twenty years 1918–37. The British Paediatric Association instituted an inquiry in Birmingham covering the years 1938, 1941, 1942, and concluded there was no evidence to show that, up to that time, war conditions had had any effect on breast-feeding (*Lancet*, 1943, **1**, 78).

There is no reason to believe that anaesthesia during childbirth has any effect whatever on lactation. Even if some analgesic drugs make the baby drowsy during the first 24 hours and this interferes with suckling during that time, it is insufficient to affect lactation.

Drunkenness and Suicide

Q.—*Do really drunk persons often attempt or commit suicide? I have just had to deal with a very drunk and depressed man, who vigorously stated his desire and intention to kill himself because of domestic worries. I do not consider him a psychotic.*

A.—The threats of the drunken need not be taken very seriously, but they should not be ignored. Suicide is quite frequent in addicts of all kinds. After dealing with the emergency, the man should be interviewed when in a state of sobriety and the degree of depression and its causes then gone into. It may then very likely appear from the sincerity of the man's manner that he is genuinely depressed, that he took to drink to drown his sorrows, and that lurking at the back of his mind is the idea of suicide, coming to open expression when alcohol had removed some of his inhibitions.

Urticaria Caused by Exposure

Q.—*A married woman of 33, accustomed to weather of all kinds, has recently developed urticarial wheals on her face after brief exposure to cold, and particularly to wind. They occur to a lesser extent in the fissures of the elbows and knees, and the forearms, thighs, and hands. She describes a feeling of heat and irritation, then numbness, as though the affected parts were frozen. The wheal stage lasts about 10 minutes, and the cold stage until she comes into room atmosphere, when it rapidly passes. In the later stage the face appears bloodless, and the affected tissues are slightly swollen and hard to the touch. The condition is a hindrance to the pursuit of her calling as a riding mistress.*

A.—The unusual condition described above may be an example of urticaria brought about by cold. The mechanism seems similar to that which causes paroxysmal haemoglobinuria, with which it is sometimes associated, a blood-carried dermolysin becoming fixed to the skin cells when the temperature is reduced, and "lysing" them when the skin is warmed, setting free H-substance, by which the wheal formation is caused. The distribution on the face and flexures corresponds to a relatively common form of eczema which may urticate and resemble true nettle-rash; but the description of the eruption—i.e., wheal formations without any accompanying eczematizations—seems to exclude an eczematous reaction of this kind. The occupation of the patient and contact with horses perhaps require further investigation.

There is no more difficult problem than the investigation and treatment of urticaria. Although less than half of the cases come into the group of allergic diseases, nevertheless non-specific desensitization may be tried, by whole-blood injections or by intramuscular injections of peptone. In others, small doses of sedatives or dilute hydrochloric acid after meals prove helpful. The application of zinc cream to the exposed skin has sometimes a protective effect. The duration of the disease is not mentioned, but it would seem to correspond with the recent cold spell.

Testosterone for Chronic Mastitis

Q.—*In the reply to the question on chronic mastitis (Feb. 3, p. 172) it is stated that conservative treatment should include the administration of hormones in suitable cases. Which hormones are indicated, and in what type of case is hormone therapy likely to be most effective?*

A.—In the type of mastitis in which both breasts feel shotty and tender, in which pain and tenderness are worse at menstrual periods, and in which there may also be abnormality of menstruation itself—commonly menorrhagia—hormone treatment is often effective. Testosterone ointment can be used with benefit; and when given by inunction there is not sufficient of the substance absorbed to produce the undesirable effects which may follow larger doses of testosterone.

Calcium for Rickets

Q.—*Is there any evidence that intravenous or subcutaneous injections of collosal calcium or calcium borogluconate are of value in the treatment of rickets?*

A.—There is no evidence that the intravenous or subcutaneous injection of calcium compounds is of value in the treatment of rickets, which is a disease due to vitamin-D deficiency. No amount of calcium in the absence of sufficient vitamin D will cure rickets. If, however, there is any evidence of deficiency of calcium as well as of vitamin D, it is advisable to supplement the diet with the former, best given orally as calcium phosphate grains 10 daily.

Loss of Spatial Orientation

Q.—*A man aged 75, previously in good health, had while bending down an attack of momentary impairment of consciousness followed by loss of vision. Ten days later he was found to have bare perception of fingers; there is a general restriction of the peripheral field of vision, almost a bitemporal hemianopia. He has lost his sense of spatial orientation (he cannot point to the door though sitting in his accustomed chair in his own room, and he cannot visualize the relationships between his cottage and the other buildings in the hamlet in which he has lived all his life). The nervous system is otherwise normal; there is no astereognosis; the disks and fundi are normal except for slight arteriosclerosis; and the blood pressure is 180/110. Could you tell me where his lesion is most likely located and what is the prognosis for recovery of vision?*

A.—The loss of spatial orientation gives a clue to the location of the lesion in this case. This symptom is always the result of a lesion in the parieto-occipital region, usually on the left side in right-handed persons, though some forms of disorientation may be produced by a lesion of the same area in the right hemisphere, and there is evidence that the most severe spatial disorientation is produced by bilateral lesions. A lesion of the left parieto-occipital region would be likely to produce a right homonymous hemianopia and would not explain the loss of vision in both temporal fields. The most likely explanation in the present case is that there was a previous patch of vascular softening in the right parieto-occipital region causing a field defect which had passed unnoticed until a fresh lesion on the left side caused the spatial disorientation and added to the visual-field loss.

Regression to Infantile State

Q.—*A little girl just under 2 years old pulls out a lump of her hair, screws it in a ball with her hand, sucks her thumb, and at the same time rolls the hair with the remaining fingers. She also does this with any lumps of fluff that may be handy, such as bits of a blanket, cotton-wool, etc. She is a normal healthy child, and only does this when alone in her pram or in bed, in spite of other attractions such as toys.*

A.—This (or similar activities) is a common practice among children. It is simply a recapitulation of the infantile state at the breast. The infant at the breast not only sucks the nipple, but often "kneads" the breast with its hands, which is probably a biological movement of squeezing the milk out of the breast. This child, deprived of the breast, is indulging in breast activities with breast substitutes—the thumb for the nipple, the hair for the breast (it is often a silk handkerchief or a satin quilt—anything, in fact, that has the soft, smooth feel of the breast). It is characteristic that this activity takes place when she is alone or in bed—that is to say, when inactivity facilitates a regression to the infantile life. It is best to do nothing at all rather than do anything to annoy the child, which will make her cling all the more to the "breast" of which she feels deprived; and she will probably grow out of it. But the gradual substitute of some other loved object like a teddy bear will facilitate the break-away.

Obesity after Parturition

Q.—*A primipara aged 23 whose periods were previously irregular (28–36 day cycle) gave birth to a healthy child 6 months ago. She was unable to breast-feed it. When lactation failed after 5 days she had a short course of stilboestrol. Her periods returned after 3 months but her cycle has been even more irregular (40–50 days). She has gained 1 st. since parturition. Should endocrine therapy be undertaken?*

A.—This seems to be a case of anterior pituitary deficiency, as evidenced by the scanty periods, rapid gain in weight, and the failure of lactation. It would be well to exclude a pituitary tumour by an x-ray examination of the sella turcica. It must be remembered, however, that irregular menstruation is frequently a feature of the first year after parturition, even in the absence of lactation. The most urgent symptom in this case seems to be the rapid gain in weight. The patient should be put on a diet consisting strictly of 1,000 calories until the weight has returned to normal. Small doses of thyroid may also be helpful. It is often found that when the metabolic disturbance is corrected in this way menstruation also becomes normal. If this does not occur in this case, it would be worth while to try the effect of small doses of stilboestrol—say, 2 mg. a day for one week in every four. Success may also be achieved with anterior pituitary hormones, and a preparation which combines the anterior pituitary follicle-stimulating hormone with luteinizing hormone from pregnancy urine has proved useful in many cases. As an alternative, small doses of *x* rays to the pituitary and ovaries often give good results. In the dosage employed for this purpose the treatment seems to be safe in the hands of experts.

Intercourse after Caesarean Section

Q.—*What time interval should elapse between (a) classical Caesarean section, and (b) lower-segment Caesarean section, and sexual intercourse—i.e., if post-operative recovery is satisfactory?*

A.—In an answer to a recent question on the resumption of coitus after natural delivery (*B.M.J.*, 1944, **2**, 874); the opinion was expressed that for the average case it is reasonable, and permissible, without risk one month after delivery. After Caesarean section the incision in either the upper or the lower segment heals rapidly, and its presence does not alter the position to any great extent. In the lower-segment operation, however, the cellular tissue in front and at the side of the supravaginal cervix is opened up, and small haematoma formation and low-grade cellulitis at that site are always possible. These may be slight and not sufficient to give rise to any clinical signs, but an early resumption of coitus might cause an exacerbation. There is, therefore, something to be said for deferring coitus for a longer time after lower-segment than after upper-segment Caesarean section (say, 6 weeks and 4 weeks respectively). When such a time has elapsed the most important consideration is the general well-being of the woman, and it is only to be expected that it will take longer for her to become strong and fit after Caesarean section than after normal delivery. This, however, is not always the case and there are wide individual variations. It is difficult to generalize on such a matter, and every case must be judged on its merits. Perhaps the best guide is the woman's own desire; so a patient could be told that after 4 or 6 weeks coitus is safe, and thereafter she should follow her natural inclinations.

Gold, Jaundice, and Tuberculosis

Q.—*I have been giving small doses of a gold compound for 6 months to a woman aged 33 with pulmonary tuberculosis and diabetes mellitus. She had a severe attack of infective jaundice (two other cases in the same house). What interval should elapse before resuming the gold compound? She is an intelligent woman and controls her diabetes completely with insulin and diet.*

A.—When jaundice occurs during antisyphilitic treatment it is generally agreed that arsenicals may be resumed when the patient has been free from all signs of jaundice and disturbed function of the liver for at least a month—i.e., about three months after the acute attack. Gold is probably less hepatotoxic than arsenic, and the same rule might therefore be applied in the present case

Sterility after Orchitis of Mumps

Q.—*A man now aged 34 years had mumps with severe orchitis in 1938. He has been married for 6 years and is anxious to have a family. His testes are small and atrophic, and examination of the seminal fluid shows complete absence of spermatozoa. He states that his testes were of normal size previous to having mumps. Is it likely that he will ever have a family? Would he benefit by hormone treatment, and if so, what?*

A.—It is unlikely that this patient will ever be able to have a child, even if he submits to long and expensive treatment. At the present time we have no hormone which is very successful in stimulating the activity of the tubules, and those which are being employed are usually very expensive. I would advise this patient to accept the fact that he is sterile.

Erythrocyanosis Crurum Puellarum Frigida

Q.—*Will you discuss the aetiology and treatment of the disfiguring condition known as erythrocyanosis crurum puellarum frigida?*

A.—The deformity is almost entirely confined to women, and especially young women, and consists of a permanent chilblain-like erythema of the ankles and legs. Parkes Weber attributed the condition to a change of fashion—short skirts and thin stockings—and it is a fact that it first appeared when this new mode of dress was adopted. Many explanations have been offered, but probably the constant change in the temperature affecting an extremity seems the most plausible; on the other hand, the erythema persists throughout the summer. As the most logical remedy—the wearing of warmer and longer garments—is never adopted, the next best is probably infra-red light and massage. Ganglionectomy is likely to fail, and is at best only of temporary benefit. The number of different forms of treatment recommended is evidence of their general inadequacy

"Under the Influence"

Q.—*A doctor may be asked to examine a person alleged to be under the influence of drink (a) who is known to him, and (b) who is a complete stranger. What constitutes a sufficiency of medical evidence in court to ensure conviction in a case of drunkenness? What clinical examination and investigation must be made by the doctor to enable him to present a case which will withstand the attack of cross-examination?*

A.—It is immaterial, from a legal standpoint, whether the practitioner knows the person to be examined or not, but if private information likely to affect the issue has been acquired in the confidential doctor–patient relationship it is advisable that he should refuse to undertake the examination.

It is asked what medical evidence will secure conviction in a case of drunkenness. If the person is drunk there is usually no difficulty in arriving at a definite conclusion, but the case is otherwise when he is charged with being "under the influence of drink to such an extent as to be incapable of having proper control of a vehicle," as is the case under the Road Traffic Act, 1930, in which only a moderate amount of drink has been taken.

There is no specific sign or symptom of alcoholic intoxication It is a gradual process and varies in different individuals to a remarkable extent. Diagnosis depends upon the consideration of a number of signs and symptoms, no one of which by itself can be relied upon. These have been well described in the *B.M.J.* of Feb. 19, 1927 (p. 345), which the questioner should consult. In general, it will be found that there is a definite smell of stale alcohol in the breath, alteration of behaviour, slight difficulty in articulation, loss of memory for recent events leading up to the accident, tremors of the tongue, lips, or hands, hiccup, suffusion of the conjunctiva and watering of the eyes, difficulty in co-ordination shown by slight swaying in the Romberg test, fumbling when bending down to pick up a small object from the floor, clumsiness in manipulating small objects on the desk, a tendency to sway when turning quickly after walking across the room, clumsiness in handwriting. The blood pressure is usually reduced and the pulse rate increased, and the temperature tends to be subnormal. The pupil is sluggish in reaction. In addition to the observation of these tests a sample of blood should be taken for chemical examination if this is possible. If not, the urine should be examined. The amount of alcohol present in the blood or urine gives a precise indication of the amount in the body at that time and forms extremely useful corroborative evidence. Ordinarily, if there is anything approaching 0.15% of alcohol in the blood the person is "under the influence of alcohol."

Sedatives for Sudden Grief

Q.—*What is the best way of dealing with acute grief, caused, for example, by the sudden and tragic death of a husband? Should sedatives—e.g., bromides, chloral, phenobarbitone—be given immediately, or withheld until the initial mental shock has given place to realization? Is there any foundation for the saying, "She must weep or she will die"?*

A.—There can be no fixed answer to this question. If the capacity to bear grief is sufficient to do without drugs, so much the better. Loss of a night's sleep does no harm to a healthy person and may pave the way to healthy fatigue and forgetfulness. If, however, the sufferer asks for a hypnotic, there is no reason to withhold it. The best choice is a quick-acting barbiturate, such as nembutal grains 3 or medinal grains 10. The hypnotic, if used, should be given at whatever time after the blow the symptoms demand it. The full realization of tragedy may come to some persons at once; for others it may be delayed, so that a dazed state may precede the appearance of acute grief. The expression of grief in weeping, however, is not necessary for its healing. The hypnotic, when it is needed, secures not only the relief of anguish, but, what is more important, the sleep which is necessary for the fullest psychological adjustment in the day, and from day to day. Sedatives in the day-time are best avoided as interfering with the process of normal adjustment.

LETTERS, NOTES, ETC.

Case of Peritoneal and Pleural Effusion

Dr. H. C. MUKERJI (Maidstone) writes: Referring to a case of peritoneal and pleural effusion (Feb. 17, p. 245), may I suggest that one of the commonest pathologies for such a case is tuberculosis. I have at the present time a similar case in hospital. He is a man of 27, with tuberculous peritonitis, and the past *x*-ray films of his chest show bilateral pleural effusion, which cleared up in a month. Incidentally the amount of free fluid in his peritoneal cavity has also decreased perceptibly. This is not an isolated case. I am collecting a series of similar cases, and hoping to write them up in the near future. Lymphocyte count and animal inoculation of "fluid" in such cases are of great help.

Oxalated Blood for Cell Counts

Dr. S. F. MARSHALL (London, W.1) writes: I should like to support what Dr. C. J. C. Britton says (Jan. 20, p. 106) on this subject. There has been much unwarranted criticism of what is a very useful method. It is, of course, granted by all that direct collection of blood is the ideal, but where this is not possible one has cause to be grateful for this alternative. As Dr. Britton says, the usual cause of error is the use of excessive oxalate for the amount of blood sent, the so-called "knife-point" added to tubes being usually in the nature of half a teaspoonful. Where the correct amount is used the next common source of error is failure to shake the tube adequately at once by the person taking the blood, or again at the time of making the actual dilution for the count. Films should be made direct, and, where this has not been done, immediately on receipt. The polymorphs soon degenerate, whereas the lymphocytes appear hardier. The nuclei of the former become round and densely staining after a few hours, causing difficulty in distinguishing the two types. Incidentally I have found that the use of potassium oxalate alone—0.5 c.cm. of a 2% solution evaporated in an oven at 120° C. for 10 to 15 minutes in the blood tube—appears to cause no change in shape or size of the red corpuscles. I have carried out many hundreds of counts with this, one advantage being that blood urea estimation may be made on the same sample if needed. This amount of oxalate—10 mg.—is as before made up for exactly 5 c.cm. of blood.

Romberg's Sign

Dr. A. WATT (Grimsby) writes: As many must have noticed, the omission of any reference to vestibular afferents in the answer to the question on this sign (Jan. 20, p. 106) does not allow the complete physiological picture to be drawn. Whereas this does not affect the reply to the first part of the question, it does nevertheless render incomplete that given to the second, as certain pathological possibilities are not thereby allowed for. In health, three groups of afferent impulses provide the intelligence which the brain draws upon to order the maintenance of posture. These are: (*a*) kinaesthetic impulses (joints, tendons, etc.) and deep pressure from the soles of the feet; (*b*) visual sensation; (*c*) impulses from the semicircular canals. Provided always that the afferent pathways and the structures actuated thereby are functioning, only two of these three groups are necessary. In the event of contradictory information from the three being received (as, for instance, experimentally, or in attacks of vertigo, etc.) the relative strength of the stimuli decides whether the response shall be the maintenance or loss of posture. The sufferer from tabes, etc., falls on carrying out Romberg's test as he is left with *c* only. But a positive Romberg's sign would also be given by an individual who had lost *c* through disease, having to rely on *a* alone. Thus the sign merely demonstrates that *a* or *c* is missing, and to decide which a further test becomes necessary. Any method of disturbing the semicircular canals will suffice—for example, the well-known one of instructing the patient to walk around an upright walking-stick held by him on the ground with his forehead resting on the handle. After five turns he is asked to stand upright with his eyes open. The tabetic, etc., will immediately fall, in fact may have been unable to complete the test, whereas he whose vestibular sensation is already cut off by disease will remain erect, having *a* and *b* to guide him. Theoretically this test might well replace Romberg's, but in practice it is cumbersome and great care is required in assessing the number of rotations necessary, as after ten even a healthy person will fall, since the vestibular then become the strongest of the contradictory stimuli.

Intravenous Anaesthesia for Torn Perineum

Dr. W. B. GOUGH (Birmingham) writes: I should like to add to your answer in "Any Questions?" (Jan. 20, p. 104) on intravenous anaesthesia for the torn perineum. I have tried local analgesia and for that matter analgesic doses of trilene or chloroform or no anaesthetic, and without two reliable assistants have found it impossible to be certain of getting that good exposure which is essential to a proper repair. I have, however, used evipan or pentothal 0.5-g. doses in some scores of cases with complete satisfaction to myself and the patient, even when only a relative or even no assistance is available. I do not defend this except on grounds of expediency, nor would I advise it to one inexperienced in intravenous anaesthesia, though I believe it to be quite safe. The secret is twofold. Have the patient in the lithotomy position using an obstetric helper with spreader, and then, providing there is no contraindication, give 0.5 g. as rapidly as possible; failure to do this will necessitate a larger and therefore possibly dangerous dose. I have not had any anxiety about the patient's condition nor does the uterus seem to relax. For this reason I do not consider intravenous anaesthesia suitable for examinations, versions, or forceps deliveries unless the head is low and on the perineum. The baby does not seem to be more affected by this than by volatile anaesthetics.

Myocardial Degeneration

Dr. F. E. LOEWY (London, N.W.8) writes: I should like to add mercurial diuretics to the remedies recommended for the treatment of pulmonary oedema under "Myocardial Degeneration" (Jan. 6, p. 33). These cases often have congestion of lungs and liver only without any visible oedema. I am giving neptal, starting with 0.5 c.cm. intramuscularly, besides morphine and digoxin as soon as restlessness with cough and dyspnoea at night (cardiac asthma) indicates a rudimentary oedema of the lungs. Neptal injections are repeated and increased according to the effect on urine output and general condition. They can be given at intervals of one or two weeks for several years and form one of our best means of preventing cardiac asthma and pulmonary oedema.

Herpes and Varicella

Drs. R. HUNT-COOKE and I. E. D. MCLEAN write: The following note is submitted for record, showing the relationship between varicella and herpes zoster. A Covent Garden foreman porter aged 63, retired owing to bronchiectasis and cardiac debility, developed herpes on Jan. 1, 1945. The spots were typical herpes vesicles on an inflamed base, associated with severe persistent pain causing insomnia. The eruption and pain persist to the time of writing (Jan. 28). The distribution of the eruption is the skin over the right scapula extending round to the side and front of the chest, and affects the medial and posterior parts of the skin of the right arm. A girl aged 4½ years developed varicella on Jan. 24, 1945. On that day an eruption of irritative transparent vesicles appeared without other symptoms, sparsely affecting the head, face, trunk, and limbs. These dried and were succeeded by a few more vesicles two days later. This girl was living in the same house as the patient with herpes zoster. Her parents state that she had not been in contact with chicken-pox, and no local cases of varicella are known. This child is not at school and not attending a day nursery. The conclusion is that the varicella developed from the herpes zoster and the time interval was fifteen days.

THE INCIDENCE OF PEPTIC ULCER AT ST. THOMAS'S HOSPITAL, 1910–37

BY

Sir HENRY TIDY, D.M., F.R.C.P.

Consulting Physician to St. Thomas's Hospital

Admissions for peptic ulcer to St. Thomas's Hospital between 1910–13 and 1922–37 are here examined to obtain an indication of the trends. The hospital was in military use during the irst world war, and records between 1914 and 1921 are not available or not satisfactory. Anastomotic ulcers have not been ncluded, nor have admissions for haemorrhage in which the diagnosis was not established. For the period 1910–13 the accuracy of diagnosis in the living may be doubtful. For the period 1922–37 most diagnoses were confirmed by radiographs, operation, or necropsy.

Periods of four years have been frequently used in order to obtain sufficient numbers for comparison. In 1910–13 admissions for peptic ulcer numbered 463, and in the sixteen years 1922–37 they numbered 3,336 (Table I). There are various methods by which the incidence can be recorded and charted o show the trends. By one method the actual numbers of admissions are compared, and this has the advantage of being easily followed. But accuracy of the trends and the relation of he trends to each other are dependent on the number of beds remaining reasonably constant and being approximately the same for the two sexes. For example, the total number of admissions in 1910–13 was about two-thirds of the later periods. Another method is to record the hospital admission rates—hat is, the proportion which admissions for the disease in question bear to the total hospital admissions. This method eliminates differences in the bed complements and numbers of admissions, and also gives an index which can be used for comparison between different hospitals. A difficulty of the method is to decide what admissions should be accepted for the denominator. It was decided here to omit admissions for pregnancy. A second point is that the incidence of peptic ulcer is very low under 20 years of age and total hospital admissions consequently contain a large block of dead weight in this age group. A further point is that the rates for the groups over 40 and under 40 years—the latter practically being between 20 and 40 years—should properly be calculated on the admissions in each age group. Few hospitals would be able to give such figures over a series of years without great labour. At St. Thomas's Hospital they are obtainable fairly easily between the years 1922 and 1929 (Table II). Admissions in the three age groups and for the two sexes do not differ grossly from each other. Hospital admission rates based on these age- and sex-group admissions thus show approximately the same trends and the same relation of the trends as when calculated on the total admissions for each sex, although the resulting index is necessarily different. It was therefore decided not to undertake the labour of counting such admissions. Hospital admission rates therefore, when here used, are calculated on total admissions at all ages for the sex concerned, omitting admissions for pregnancy.

The number of admissions, deaths, and hospital admission rates (H.A.R.) are recorded for four-year periods in Table III, subdivided for gastric ulcer and duodenal ulcer, sex, and age groups under and over 40 years. Annual admissions for males are recorded in Figs. 1 and 2 and for females in Fig. 3. Mean

TABLE I.—*Summary of Admissions for Peptic Ulcer*

	Admissions			Ratio ♂ to ♀
	Total	Male	Female	
1910–13:				
Gastric ulcer	319	114	205	0·6
Duodenal ulcer	144	138	6	23·0
Ratio G.U. to D.U. ..	2·2	0·8	34	(1·2)
1922–37:				
Gastric ulcer	2,189	1,580	609	2·6
Duodenal ulcer	1,147	1,025	122	8·4
Ratio G.U. to D.U. ..	1·9	1·5	5	(3·6)

Ratio of sexes gives the figure for males, regarding females as unity.
Ratio for G.U. and D.U. gives the figure for G.U., regarding D.U. as unity.

TABLE II.—*Annual Admissions by Age and Sex Groups*
(00 omitted. Includes all admissions except for pregnancy)

	Males			Females		
	Age Groups (years)			Age Groups (years)		
	0–20	20–40	40–	0–20	20–40	40–
1922	11	10	12	9	10	11
1923	13	13	13	11	13	12
1924	14	13	14	12	11	13
1925	15	14	14	12	14	14
1926	15	14	15	12	14	14

Hospital admission rates are expressed as percentages of total admissions at all ages for the sex concerned, excluding pregnancy in females.

hospital admission rates for four-year periods also are recorded in a graph (Fig. 4), and give a general view of the trends over the period.

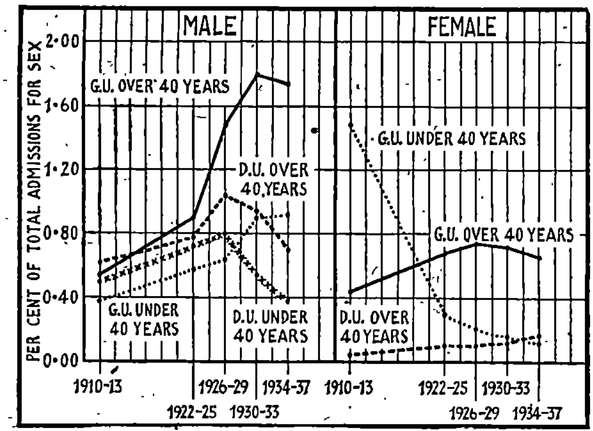

FIG. 4.—Hospital admission rates for peptic ulcer in four-year periods

General Features of the Trends of Admissions

The number of admissions, and the H.A.R. for gastric ulcer in males over 40, rose slowly from 1910–13 to 1922–5. It then rose so rapidly between 1925 or 1926 and 1929 that it more than doubled. Subsequently the rise ceased, but the level was maintained. While the rates for the four groups—viz., G.U. and D.U. under and over 40 years—in males were close together until 1925, this group now far exceeded the others. The trend for gastric ulcer under 40 years is not dissimilar to that for the older group, but the rises are less and the rates on a much lower level; the rise is slight until 1926, but there is then a fairly sharp increase to a maximum in 1929 or 1932, followed by a level rate or possibly a slight fall.

The trends for duodenal ulcer differ from those for gastric ulcer. The trends for the two age groups of D.U. are close together throughout, unlike those for G.U. There is an irregular rise in both age groups to a maximum about 1928–9. Subsequently there is a rapid fall, so that the H.A.R. in 1934–7 for the age group over 40 is only slightly higher than in 1910–13, while for the group under 40 it is definitely lower.

For females there is a spectacular fall in admissions for gastric ulcer under 40 years. While in 1910–13 it was the largest single group of peptic ulcer for either sex, it is now almost extinct. Gastric ulcer over 40 years in women showed a steady rise until 1930, but without the rapid increase seen in males and at a much lower rate. Admissions tended to fall again after 1930. Admissions of females for duodenal ulcer both over and under 40 years are very few. Both age groups show a slight, but only slight, increase. As with males, the rates in the two age groups are close together for D.U. and widely apart for G.U.

There are no other hospital statistics at present by which these results can be checked. They can be compared to some extent for certain periods with the course of the death rates for London (Administrative County), although unfortunately G.U. and D.U. are not separated in the Registrar-General's Returns after 1930 (Tidy, 1944). The death rates for London show a very sharp rise for G.U. in males over 40 years from about 1921, the rate being more than doubled by 1930 (Fig. 5). The death rate for D.U. also doubled in this period, but was throughout about half that for G.U. The rate for G.U. was still rising up to 1930, but the rate for D.U. ceased to rise after 1928. Subsequent to 1930 the combined death rate for G.U. and D.U. in this age group suddenly ceased to rise and became almost stationary.

Deaths for males under 40 years for both G.U. and D.U. are small in number, but the rate showed a slight increase for each between 1921 and 1930, then fell again, and the combined rate was the same in 1937 as in 1921.

For females, the death rate for G.U. under 40 years had fallen rapidly for several decades and was still falling in 1930. For G.U. over 40 years the rate rose 50% between 1921 and 1930. After 1930 the combined rate for G.U. and D.U. in this age group is stationary; as deaths from D.U. are almost negligible, the combined rate is practically due to G.U., which therefore could not have been rising. Thus death rates and admissions after the war both show a rapid rise for males over 40 years, which suddenly ceased about 1930. The rise and the rates in both are much greater for G.U. than for D.U., and the rise stopped earlier for D.U. than for G.U. Both death rates and admissions show a 50% rise from gastric ulcer in females over 40 years, ceasing in 1930, which does not appear in the death rates for England as a whole or for Scotland. The fall in females under 40 years is common to the whole of Britain for several decades, the most rapid fall being between 1900 and 1920. Thus where the trends of the death rates for London and of the number of admissions, or of the H.A.R. for St. Thomas's Hospital, can be compared, they are in reasonable agreement. The trend of admissions to the hospital is in closer agreement with the death rates for London than with those for England as a whole.

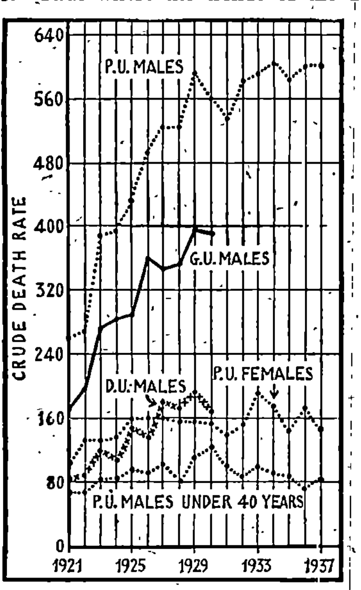

FIG. 5.—London (A.C.). Crude death rates over 40 years of age. Per million living in age and sex groups.

Ratio of Gastric to Duodenal Ulcer

The ratio has changed considerably in the course of 25 years, and consequently ratios based on a long period of years will be misleading. The ratios of G.U. to D.U. for all admissions in the four-year periods are respectively 2.2, 1.4, 1.5, 2.2, and 2.5 to 1. For the period 1910–13 the ratio was dominated by the prevalence of G.U. in young women, and the subsequent fall in the rate was due to decrease in this group. The later rises are due mainly to increase in G.U. and fall in D.U. in males. The trend of the ratios differs so greatly for the two sexes that these should be considered separately (Table IV).

TABLE IV.—*Ratio of Gastric to Duodenal Ulcer*

	Males			Females			Total Admissions
	All Ages	Under 40 Years	Over 40 Years	All Ages	Under 40 Years	Over 40 Years	
1910–13	0·8	0·8	0·9	34	160	9·0	2·2
1922–25	1·0	0·8	1·1	6·5	8·0	6·0	1·4
1926–29	1·2	0·8	1·4	6·5	6·0	7·0	1·5
1930–33	1·9	1·6	2·0	5·4	5·7	5·3	2·2
1934–37	2·4	2·1	2·5	3·3	1·5	4·0	2·5
Total 1922–37	1·5	1·2	1·7	5·0	5·0	5·2	1·9

1922–37: Females, all ages: $\chi^2 = 9{\cdot}13$, $n = 3$, $P = 0{\cdot}03$. For males, all ages, P is infinitesimal.

Figure of gastric ulcer is recorded, duodenal ulcer being regarded as unity. For numbers see Table III.

The ratio for males also varies with the age, rising progressively with each decade (Table V); but this result is based on the whole period 1922–37, during which various changes have occurred, the sum of which must be accepted with caution.

For the period 1910–13, in addition to the prevalence of G.U. in young women, it is noticeable that D.U. was in excess of G.U. for males in both age groups. For males over 40 years of age G.U. was slightly in excess of D.U. in 1922, and, after several years of equality, permanently became greatly in excess in 1927. For males under 40 years G.U. first and finally became in excess in 1929. An appreciable excess of G.U. over D.U. in males is thus a comparatively recent development in admissions to St. Thomas's Hospital, and the excess is still increasing, the ratios for all ages in the four four-year periods 1922–37 being respectively 1, 1.2, 1.9, and 2.4 to 1. G.U. was gaining over D.U. before 1930 because it was increasing more rapidly, and after 1930 because it was stationary while D.U. was falling.

TABLE V.—*Age Distribution of Peptic Ulcers and Perforations, 1922–37*

Age Group	Males							Females	
	Total Admissions		Ratio G.U. : D.U.	Perforations		Perforations % of Admission		Total Admissions	
	G.U.	D.U.		G.U.	D.U.	G.U.	D.U.	G.U.	D.U.
0–20	4	5	0·8	1	3	—	—	4	2
20–30	143	156	0·9	41	36	29	23	35	11
30–40	382	262	1·5	55	47	14·4	18	94	18
40–50	500	304	1·6	75	56	15	18	193	42
50–60	375	213	1·8	43	41	11·5	20	163	29
60–	176	85	2·1	25	22	14	26	120	20
All ages	1,580	1,025	1·5	240	205	15·2	20	609	122

Ratio of G.U. to D.U.: Figure for G.U. is recorded, D.U. being regarded as unity.

For females, G.U. has always been in excess of D.U., which is rare at any age, but the ratio has fallen from 34 to 1 in 1910–13 to 3.3 to 1 in 1933–6. The fall is principally due to the practical disappearance of G.U. under 40 years, but there may be a slight increase in D.U. Thus the ratio of G.U. to D.U. is rising for males and falling for females in both age groups. These changes are statistically significant.

Ratio of G.U. to D.U. in Private Practice

Physicians in the London area have been puzzled by the discrepancy between the ratios of G.U. and D.U. for private patients and hospital cases. Most physicians would agree that D.U. is considerably commoner than G.U. in consulting practice. There is a tendency to believe that private practice more correctly represents the ratio in the local population, and that for some reason hospital statistics are misleading. This view should not be lightly accepted. There are several factors which affect comparison between the two series.

1. Statistics of private patients are generally drawn from many years of practice, while the larger hospital statistics are usually from a few recent years. The statistics given here show how rapidly the relative incidence of G.U. in males has been rising recently among hospital patients in London.

2. Private patients are mainly drawn from a limited section of the community which falls largely into Social Class I (professional classes, etc.), while hospital patients are nearly all from Class III (skilled workers) to Class V (unskilled workers). The Registrar-General's Decennial Report, 1931, Part 2, gives the standardized mortality ratios for G.U. and D.U. for males of 20 to 65 years for the five social classes (Table VI). For Class I the rate for G.U. is 55% of the expected rate, for Class III 99%, and for Class V 127%. On the other hand, for D.U. there is no appreciable difference between the rates for the different classes. If these results apply also to the living, then D.U. in proportion to G.U. will be nearly twice as high in Class I as in Class V. (It must be noted that the actual ratios of G.U. to D.U. cannot be obtained by comparing the standardized mortality ratios for G.U. and D.U.)

TABLE VI.—*Standardized Mortality Ratios, Gastric and Duodenal Ulcers*

	Males: Age 20–65 Years				Married Women: Age 35–65 Years
	1921–23		1930–32		1930–32
	G.U.	D.U.	G.U.	D.U.	G.U. and D.U.
Social class I	72	126	55	101	53
„ „ II	87	109	76	106	98
„ „ III	96	91	99	99	99
„ „ IV	105	93	109	93	99
„ „ V	127	113	127	107	118

From the Registrar-General's Decennial Report, 1931, Part 2.

There are other factors which affect comparison of private and hospital patients, such as age and sex distribution, and the areas from which material is drawn. An urban population in England tends to have a higher incidence of G.U. than a rural area, and hospital patients are, in general, urban residents, while private patients are drawn from wider areas. Hence the ratios of G.U. to D.U. in private practice and hospital patients are not necessarily comparable.

Sex Incidence

The sex incidence differs so greatly for G.U. and D.U. that these should be considered separately. For each ulcer the ratio has changed steadily between 1910 and 1937, but in opposite directions, and the ratio for the two ulcers combined—i.e., for peptic ulcer—is of little value (Table VII). The relative incidence of males has been rising for G.U. and falling for D.U. Both changes are statistically significant. Ratios based on a long period of years may be misleading, and the common statement that the sex incidence remains constant at 3 males to 1 female gives an erroneous impression of constancy of the ratio in the two types of ulcer.

Table VII.—*Ratio of Males to Females*

	Gastric Ulcer			Duodenal Ulcer			Peptic Ulcer
	All Ages	Under 40 Years	Over 40 Years	All Ages	Under 40 Years	Over 40 Years	Total Admissions
1910–13	0·6	0·3	1·5	23	61	15	1·2
1922–25	1·7	2	1·5	11	22	8	3
1926–29	2·5	3	2·2	14	23	11	4
1930–33	2·7	5	2·2	8	17	6	3·7
1934–37	3·3	7	2·7	4·5	5	4·3	3·6
Total 1922–37	2·6	3·9	2·2	8·4	14	7	3·6

1922–37: G.U. over 40 years: $\chi^2 = 11{\cdot}47$, $n = 3$, $P = 0{\cdot}01$.
1922–37: D.U. all ages: $\chi^2 = 20{\cdot}30$, $n = 3$, $P =$ less than 0·01.
Figure for males is recorded, females being regarded as unity. For numbers see Table III

In the period 1910–13 there was little difference between the two sexes for peptic ulcer as a whole. D.U. was practically unknown in females, but in G.U. under 40 years women predominated, and formed the largest of all groups. The excess of females in this group disappeared between 1913 and 1921. The previous preponderance of this group and its rapid fall have influenced sex ratios for the last 50 years, as also the ratios for G.U. and D.U. While this group is now very small, the fall in admissions and in the hospital admission-rates can be recognized up to the last period, so presumably a few cases of the same type are still occurring. Since the disappearance of this group, males have been heavily in excess in all groups, especially at younger ages. The rarity of D.U. in women is noticeable. For D.U. under 40 years only 31 women were admitted in 1922–37, in contrast to 423 males.

Age Incidence

In the period 1922–37 admissions were highest in the decade 40–50 years, both for G.U. and D.U. and for both sexes (Table V). For females the proportion of admissions below 40 years is now less than in males, and the average age is higher (see Table II). The average age of admissions for G.U has been increasing in both sexes, but in males it has been mainly due to increasing numbers over 40 years and in females to decreasing numbers under 40 years. General estimates of age incidence based on long periods are of little value, for age incidences have been influenced by two factors which have been rapidly changing during the period under consideration. The most important is the practical extinction of the formerly predominant group of G.U. in young women. In 1910–13 and probably for some years subsequently the size of this group caused the mean age for peptic ulcer to be much lower in women than in men. In previous decades the difference was even greater. The disappearance of this group resulted in peptic ulcer in a short time becoming very rare in young women, causing a rapid rise in the mean age considerably above that for males. The rapid increase in G.U. in males over 40 years, and to a lesser degree in D.U., between 1920–30 raised the mean age for males, but it still remained below that for women.

Incidence of Perforations

In the period 1922-37 admissions for perforated peptic ulcer numbered 478. There were 263 perforations among 2,189 admissions for G.U., forming 12.1%, and 215 among 1,147 admissions for D.U., forming 19.1%. The difference between these percentages is statistically significant (7±1.31). We have no reason to believe that there was selection at any point in favour of perforated D.U. or, conversely, in favour of non-perforated G.U. On the data here available the difference may be held to indicate that D.U. has a greater liability to perforate than G.U. This is in accordance with the general belief of clinicians, but is a provisional suggestion on the present data. The differences between the percentages of perforations to admissions for G.U. and D.U. are significant separately for males (4.8±1.54) and for females (4.4±2.06).

Among males G.U. perforations numbered 240 and D.U. 205, and among females G.U. numbered 23 and D.U. 10. Males constituted 91% of admissions for perforated G.U. and 95% for D.U. This high proportion in males is not wholely accounted for by the greater incidence of peptic ulcer. Perforations form 17% of male admissions and only 4.5% of female. The difference in the percentages between the sexes is statistically significant both for G.U. (11.4±1.55) and for D.U. (11.8±3.74). There is no reason to believe that there was any selection which would influence these results. The difference may be held to indicate that, given an ulcer is present—either G.U. or D.U.—the liability to perforate is greater in a male than in a female.

Table VIII.—*Incidence and Mortality of Perforations*

	Period	Under 40 Years				Over 40 Years				Total Perforations

For number of cases (admissions of ulcers) see Table II.

The highest number of perforations in males was in the age group 40–50 years, both for G.U. and for D.U. (Table V). For females the numbers are too small for subdivision, but perforations are very rare under 40 years.

The proportion of perforations to admissions for males is the same in the two age groups for D.U. For G.U. it is higher under 40 years than over 40 years, and the difference is significant (5.2±1.92). Over 40 years the proportion has apparently been falling. The higher proportion of perforations to admissions under 40 years for G.U. is entirely due to the decade 20–30 years, which is nearly twice as high as any of the succeeding decades, between which the difference is not significant. Nor is the difference significant between any of he decades for D.U. This uniformity for D.U. throughout ife is consistent with other evidences given in this communication. So also is the distinction of G.U. into two age groups, but the indication here suggests that the dividing line is nearer 30 than 40 years.

There were 98 deaths among 445 male perforations, the case mortality at all ages being 22%. For G.U. the rate is 24.6% and for D.U. 19%. For D.U. there is no difference in the case mortality in the age groups. On the other hand, for G.U. there is a marked difference, being 34% in the older group and 10% in the younger, and the difference is statistically significant. A higher case mortality for G.U. perforations than for D.U. is well recognized, and also a rising case mortality with increasing age. The absence of increase for D.U. in the later age group is unexpected, and more data are desirable.

There were 12 deaths in 33 female perforations, only one death occurring under the age of 40 in the 16 years.

For the period 1910–13 perforation has a high case mortality, as would be expected. While statistics at this period must be accepted with caution, the number of perforations from G.U. in women under 40 years may be accepted as substantially correct, since this was a well-recognized lesion. In this group, among 160 admissions, there were 19 perforations with 6 deaths. This is the highest number of perforations in any group of G.U., but they form only 12% of admissions—a proportion lower than any other group. The view often accepted that this type of ulcer had a special tendency to perforate, with a high case mortality, is not supported by these figures. The differences between the groups are not significant. The large number of perforations from D.U. in males over 40 years in this period is noticeable, and the allocation for D.U. apparently is supported by the cases in which necropsies were performed. If this series is reliable a rapid change in the incidence of perforation of D.U. took place between 1913 and 1922 or in the type of ulcer, but although the change is statistically significant, further data are necessary.

Recurrence of Perforation.—For the period 1933–6, of the 392 admissions for G.U. in males, excluding admissions for perforation, 16 had previously perforated, and of 170 similar admissions for D.U. 9 had done so. Of the 70 admissions for perforated G.U. 3 had previously perforated, and of the 38 admissions for perforated D.U. 2 had perforated, none of these being fatal. The proportion of these earlier perforations is about the same in the two groups. No woman had previously perforated.

Duration of Symptoms before Admission

The duration of symptoms in males before admittance has been calculated from admissions to St. Thomas's Hospital for 1933–6 and, in order to obtain additional material, from a number of admissions to Army hospitals in 1941 (Table IX):

TABLE IX.—*Duration of Symptoms Previous to Admission (Males)*

	Age Groups (Years)				
	20–30	30–40	40–50	50–60	Over 60
Gastric ulcer:					
Under 4 years	56 (30)	46 (61	47 (56)	41 (39)	50 (28)
4–9 years	30 (20)	28 (37)	30 (37	31 (30)	17 (9)
10 years and over ..	10 (7)	26 (34)	23 (27)	38 (27)	33 (18)
Mean duration (years) ..	4½	6	6	6	6
Duodenal ulcer:					
Under 4 years	48 (124)	40 (112)	38 (45)	33 (14)	20 (3)
4–9 years	43 (112)	35 (110)	23 (27)	29 (12)	40 (6)
10 years and over ..	9 (25)	25 (73)	39 (46)	38 (16)	40 (6)
Mean duration (years) ..	4	6	7	7	8

Distribution of duration recorded in percentages for each age group. Actual numbers in brackets. Admissions for perforated ulcers are not included.

For G.U. the duration before admission does not increase after the age of 30. There is a material proportion with a comparatively recent onset even in the later age groups. For D.U. the previous duration tends to increase with age, and there is a higher proportion of lengthy durations and a progressive decrease in the proportion of short histories. It would appear that a high proportion of cases of G.U. met with in the later age decades have started after middle life and that the common course for younger patients is to recover either completely or sufficiently not to require subsequent hospital treatment. This is undoubtedly true for the type of G.U. formerly prevalent in young women.

Deaths and Case Mortality

The causes of death will not be considered here, other than the above references to perforation.

In the period 1922–37 there were 333 deaths in 3,336 admissions—a case mortality of 10% (Table III). The case-mortality rate varies greatly with the age, and to some extent with the type of ulcer and the sex. In the age groups under 40 years the rate is about 5% in each group, while over 40 years it is 12.3%. In women under 40 years only 9 deaths occurred among 164 cases. In the age groups over 40 years the case-mortality rate is higher for males (13.3%) than females (9.5%), and for G.U. (12.8%) than D.U. (11.2%). For males the rate is 14.1% for G.U. and 11.8 for D.U. The difference between males and females is significant (3.8±1.59); the other two are not significant.

Comparing four-year periods, the case-mortality rate from G.U. in males over 40 years has fallen steadily from 19.4% in 1922–5 to 11.6% in 1934–7. The difference between 19.4 and 11.6 is significant (7.8±3.5), but the differences between the four columns are not statistically significant to the χ^2 test. ($\chi^2=5.21$, $n=3$, $P=0.15$.) This, however, takes no regard for the order of the numbers in a progressive fall. This can be corrected by the formula $\frac{P}{\underline{|n+1}}$, where n is the number of columns as counted in the χ^2 test. This reduces the value of P from 0.15 to 0.006, which is significant. Hence it appears that the progressive fall is significant. Various reasons could be suggested for this, such as improved surgical and medical treatment. For D.U. there has been no fall in case mortality. The case-mortality rate for 1910–13 is considerably higher than for later periods. The rate for G.U. in females under 40 years is distinctly lower than for other groups, and supports the comparative mildness of this type of ulcer.

Discussion

Any attempt to follow the trend of peptic ulcer must consider G.U. and D.U. separately and also subdivisions for sex and age. The present communication solely applies to the London area. Even with this proviso, admissions to a single teaching hospital are not necessarily a random sample of the area. Until further data are available certain deductions are only provisional. Nevertheless the broader outlines here presented of the picture and of the trends may be useful. In certain groups the trends of the hospital admissions can be compared with the trends of the death rates for London and for England and are not inconsistent.

Two special factors influence the trend of peptic ulcer during the period of 1910–37. One is the rapid decrease of gastric ulcer in young women in the earlier years of the period, and the other is the rapid increase of gastric ulcer in older men between 1922 or 1925 and 1930.

The fall in the incidence of gastric ulcer in young women is confirmed by the trend of death rates for all parts of Britain. The decrease of perforations in this group has long been clinically recognized (Jennings, 1940), but it is evident from the trend of hospital admissions that such decrease is the result of a fall in the incidence of this ulcer and not due to a change in its liability to perforate. The fall for admissions, perforations, and death rates was largely completed by 1922, but still continued until 1937, and it greatly influences all long-period ratios of G.U. to D.U., males to females, and age incidences. This was the largest group of peptic ulcer until about 1914, but its fall probably began about 1900, its incidence in the nineteenth century having been even greater. The disappearance of this group establishes that some set of removable external aetiological factors can rule the incidence of one type of ulcer in one sex at one age period, and if this is true for one group of peptic ulcer it can be true for others. A further question which may be referred to here is the fate of this group of young women. They did not die, since the case mortality is low. Nor did the ulcers become chronic, for in the period 1910–13 there were 160 admissions under 40 years and only 45 over 40 years, and the young cases were not readmitted for recurrences. The only remaining substantial possibility is that the ulcers healed and did not recur.

A rapid rise in admissions for G.U. in males over 40 years started about 1925 and ceased about 1930, when the curve flattened out. A rapid rise in death rates in this group for all parts of England but greatest in London began about 1922 and ended about 1930. This group, both for admissions to St. Thomas's Hospital and for death rates for London, and also for death rates for England, had then outstripped all other groups of peptic ulcer.

Admissions for G.U. in males under 40 years also rose rapidly between 1925 and 1930, but there are certain differences between the two age groups. The rise is less marked. There is a wide interval between the curves for these age groups. The duration of symptoms previous to admission is comparatively constant throughout the two age groups, and suggests that the older group is not due materially to continuation of symptoms arising in the younger ages, but to new formations of ulcer. This difference between the two age groups for G.U. in males is even more marked in females, in whom the trends are clearly completely independent.

The trends of admissions for D.U. differ from those for G.U. Admissions in males are close together in the two age groups. There is a progressive increase in the duration of symptoms in the age groups, and an increasing proportion of cases with lengthy histories. Admissions for D.U. in males rose irregularly to a maximum about 1928–30. Subsequently there was a fall until the hospital admission rate finally was below that for 1910–13. Admissions commonly exceeded those for G.U. until 1926. The curve for G.U. over 40 years then finally passed the corresponding group and rose far above it. The curve for G.U. under 40 years passed D.U. under 40 years in 1929.

If the trends of admissions to St. Thomas's Hospital are a reflex of trends of morbidity in the population drained they suggest that the incidence of G.U. in males over 40 in the London area rose rapidly about 1925 and suddenly ceased to rise about 1930, though the maximum rate was maintained, while the incidence of D.U. in males rose moderately during a shorter period, but subsequently fell again to the level of 1910–13. Such trends and the recent great and increasing preponderance of G.U. over D.U. may be unexpected, but they are consistent with the trends of the death rates.

For females the only considerable group of peptic ulcer in recent years is gastric ulcer over 40 years of age. Admissions show a steady but moderate increase to a maximum in 1930, with a subsequent fall. This trend agrees with death rates for the London area, but neither England as a whole nor Scotland shows any rise in death rates. All other groups of peptic ulcer are now rare in women. The incidence under 40 years is low, and the mean age, which before 1913 was below that for males, is now higher.

The proportion of cases admitted for perforations varies in different groups. It is suggested that in the absence of evidence of selection a higher proportion indicates a greater liability to perforate. Differences referred to here are all statistically significant. The proportion is higher for D.U. than for G.U. in both age groups. For D.U. the proportion is the same in the two age groups, but for G.U. it is higher under 40 years than over 40 years. The case-mortality rate for all ages is higher for G.U. than for D.U. This is due to the high case mortality for G.U. over 40 years, which is three times greater than in G.U. under 40 years. The case-mortality rate for D.U. in this series is the same in both age groups. These differences between perforations in the two age groups for G.U., together with other differences referred to above, will be held to indicate the presence of different aetiological factors at different ages. For D.U. there are no such differences.

The proportion of cases admitted for perforation is lower in females than in males for both G.U. and D.U. Perforations in women are now rare. Thus it appears that in women not only is the development of ulcer now comparatively rare but, when present, an ulcer has a low liability to perforation. Possibly the factors which determine formation of an ulcer and perforation are not necessarily identical.

It is generally agreed that the aetiological factors of G.U. and of D.U. are different. Clinical evidence for this is accumulating. There are differences in the trends of the death rates for the two types in England and between England and Scotland, and differences in the standardized mortality ratios for the five social classes. Various differences in the two types for admissions, perforations, and case mortalities are recorded here. For G.U. there are also differences between the age groups. It may be suggested that there is more than one group of aetiological factors producing G.U., operating commonly at different ages and differently in the two sexes. For D.U. there are no such differences between the age groups, which suggests that the same set of factors operates at all ages but with widely different effects on males and females.

Psychoneurotic stimuli often appear to be the exciting cause of the development of D.U. and of the incident of perforation. As a sole factor this theory does not explain the rarity of D.U. in women and the even greater rarity of perforation. The severest air raids scarcely shook the curve of perforations in women, but they sent the curve for men sky-high. Nor is it consistent with the practical absence of D.U. before 1900 and its subsequent trends. Some independent predisposing cause is indicated. Psychoneurotic stimuli may pull the trigger, but some other hand has previously loaded the gun.

The external factors concerned in the development of gastric and duodenal ulcer cannot even be adumbrated here, but a study of the changing face of peptic ulcer and of its different aspects in various geographical areas may assist in their elucidation.

Conclusions

1. Admissions for G.U. in males over 40 years increased rapidly between 1925 and 1930, when the rise ceased but the maximum rate was maintained. Admissions under 40 years had a somewhat similar trend, but with much lower numbers. There are certain differences between the features of the two age groups.

2. Admissions for D.U. in males rose irregularly and moderately after the war until 1929–30 and then fell again to the level of 1910–13. Admissions in the two age groups under and over 40 years are similar in number and trends.

3. Admissions for G.U. in males have been in excess of those for D.U. since 1927, previously having been less, and the excess has been rapidly increasing. Under 40 years, G.U. first became in excess of D.U. in 1929.

4. The trends of admissions for G.U. in females are completely independent in the age groups under and over 40 years.

5. Admissions for G.U. in females over 40 years increased moderately until 1929–30, when the rise ceased.

6. Admissions for G.U. in females under 40 years formed the largest group of G.U. in 1910–13, but fell rapidly, and the incidence is now very low.

7. Admissions for women are very low for D.U. at all ages.

8. The trends of hospital admissions and of death rates for London (Administrative County) are reasonably in agreement.

9. The ratio of G.U. to D.U. is rising for males and falling for females.

10. The ratio of males to females is rising for G.U. and falling for D.U.

11. The ratios of G.U. to D.U. in hospital admissions and in private practice are not comparable.

12. The liability of an ulcer to perforate is greater in D.U. than in G.U., and greater in males than in females for both G.U. and D.U. For G.U. the liability is greater under 40 than over 40 years; for D.U. it is the same in both age groups.

13. The case-mortality rate of perforated G.U. is considerably higher over 40 than under 40 years. For D.U. it is the same in both age groups.

14. The factors stimulating the formation of peptic ulcers are different for G.U. and D.U. For G.U. they are not the same for the age groups under and over 40 years. For D.U. they are similar for both age groups, but have little influence on women.

BLACKWATER FEVER IN WEST AFRICA

BY

E. W. SKIPPER, M.D., M.R.C.P.

Lieut.-Col., R.A.M.C.; Officer in Charge of a Medical Division at a Military Hospital

AND

G. L. HAINE, M.B., B.S., M.R.C.S.

Capt., R.A.M.C.

For a period of 20 months we were stationed at a general hospital in one of the West African colonies. This hospital was situated in well-drained uplands, its precincts being practically free of the anopheline mosquito, but within two miles the hills descended into large areas of swampy ground where subtertian malaria was rife. Most of the cases of malaria and all the cases of blackwater fever treated in this hospital came from these areas. During the 20-month period 2,355 cases of subtertian malaria in British and Allied personnel were admitted, the majority being from the British Army. In the same interval 7 cases of blackwater fever were admitted. There were no deaths from either disease. These cases of blackwater fever are presented because it is felt that this disease is of special importance while British and Allied troops are living and fighting in countries in which it occurs, and because it is not very rare for individuals to develop it after return to the United Kingdom from the Tropics. Such a case, rapidly fatal, was seen by one of us. An account of the clinical features and treatment of subtertian malaria in British troops in West Africa has already been given by Hughes and Bomford (1944).

Blackwater fever is a disease characterized by a sudden intravascular haemolysis, with the liberation of oxyhaemoglobin in the plasma. From this, methaemoglobin and methaemalbumin ("pseudo-methaemoglobin") are formed. Oxyhaemoglobin and methaemoglobin are excreted in the urine together with acid haematin, these blood pigments imparting the typical porter or stout colour to the urine. Methaemoglobin, with its much larger molecule, is never excreted. The two most important characteristics of the disease—namely, the haemolysis and the anuria—will be separately discussed.

Relationship to Malaria

Blackwater fever is now universally regarded as a complication of malaria, especially of the subtertian form. Stephens (1937) was able to collect only 7 cases in which it was associated with benign tertian or quartan fever. A fatal case following *P. ovale* infection is quoted by Fairley (1939). It is met with in those countries in which subtertian malaria is hyperendemic, and, as it principally affects the white races in such countries, has long been the dread of Europeans on the West African coast, being in part responsible for the unhealthy and somewhat sinister reputation enjoyed by that part of the continent. It is interesting to note that in the 20-month period only 168 African soldiers were admitted with malaria, although the total African admissions for all diseases far outnumbered the British. The West African, if he survives malaria in infancy and childhood, becomes relatively immune to it. We heard of no case of blackwater fever in a native soldier, but there were several among the Syrian settlers in the colony. It is generally stated that the seasonal incidence of blackwater fever closely follows that of subtertian malaria. This has certainly been our experience in this small series. In this colony malaria was endemic throughout the year, but it reached its peak in July and August—i.e., at the height of the rains—and five of our cases developed blackwater fever in July, August, or September.

All our cases had had previous attacks of malaria (Table I). Case VII had had only one recognized attack, but had taken no suppressive quinine, and there was reason to believe he had been very careless over antimalarial precautions in general. His malaria had been treated at another hospital with 30 gr. of quinine daily for 2 days, 0.3 g. of mepacrine daily for 5 days, and 0.03 g. of pamaquin daily for 4 days. The haemoglobinuria developed on the day after completion of the above treatment. Case III had been treated in our hospital for the sixth attack of malaria with 10 gr. of quinine and 0.3 g. of mepacrine daily for 7 days, followed by 0.03 g. of pamaquin daily for 3 days. This patient was perfectly well when discharged, but he got wet through on the way back to his unit and was readmitted with blackwater fever the same evening. Three patients developed the disease during actual treatment for malaria in our hospital. In all of them the urine had been normal before the onset of the haemoglobinuria and had been kept alkaline. Thus, Case I developed it on the second day of treatment after a total of 60 gr. of quinine, Case IV also on the second day after 30 gr., and Case V on the seventh day after 150 gr. of quinine and an intramuscular injection of 0.2 g. of mepacrine hydrochloride. The latter was given as the temperature, which had almost settled, rose suddenly to 104° F., this rise probably corresponding to the onset of the haemolytic process. Haemoglobinuria followed two and a half hours after the injection. This patient was also receiving treatment for amoebic dysentery. These three cases, and also Case III, had not been thoroughly treated for previous attacks of malaria. We are of the opinion that the fact that blackwater fever may arise during what appears to be an ordinary uncomplicated attack of malaria has not been sufficiently stressed; there has been too great a tendency to regard it as developing only in subjects with malarial cachexia who have been resident in the Tropics a long time. Three of our cases had been in West Africa for less than one year. We were unable to recognize a "pre-blackwater fever" stage in any of those who developed the disease in hospital. Conversely, we saw many malarious patients in whom the cachexia and history of previous attacks led us to believe they were likely candidates for blackwater fever but who did not, in fact, develop it.

Clinical Features

A full account of these may be found in standard works. The most important biochemical and other details of our cases are summarized in Tables I and II.

TABLE I

Case	Age	Residence in W. Africa	Previous Attacks of Malaria	Suppressive Quinine
I	25	20 months	2	Regular
II	20	8 "	2	"
III	27	16 "	6	"
IV	31	11 "	7	"
V	23	19 "	5	Irregular
VI	36	18 "	5	Regular
VII	20	6 "	1	None

A rigor, said to be typical of the onset, occurred at the beginning of the illness in one patient only. Of the cases which developed blackwater fever during treatment for malaria, Case V, as already stated, showed a sudden rise of temperature with the onset of haemoglobinuria. In Cases II and IV the temperature also rose to 102° and 104° F. respectively. These three patients also showed a very abrupt rise in the pulse rate. Such an increase in the rate of the characteristically slow pulse of malaria is of importance, and should lead to an immediate examination of the urine for haemoglobin. Except in Case I, a rapid pulse of 100–120, of poor volume, was a constant feature in all the patients. The duration of the fever corresponded to the acuter stages of the disease, except in Cases III and IV, in which a fever of 99–99.5° F. was prolonged well into convalescence—the so-called "post-haemoglobinuric fever." Only Case I was afebrile throughout.

The jaundice, together with anaemia and cachexia, imparted a characteristic appearance which sun-tan rendered all the more striking. The general impression obtained was of great weakness; these men were disinclined to move, and a constant complaint was of feeling "very ill." In no instance was the liver palpable, although tenderness over it was elicited in three instances. In Cases II, IV, and VII the blood pressure was low during the first few days, readings of 96/40, 92/45, and 94/90 respectively being obtained. In Case VI the blood pressure, which was 108/66 on the second day of the illness, rose at the same time as the blood urea to 150/80 on the ninth day. A leucocytosis of 25,000 and 30,000 occurred on the first and fourth days respectively in Cases V and VII. Cases VI and VII developed a reticulocytosis of 5% and 9% respectively during recovery from the anaemia. Convalescence was prolonged, the average length of stay in hospital being 45 days. All patients were invalided to the United Kingdom with a recommendation that they should not again be sent to a malarious country.

The mortality varies from 25 to 50%, according to different authors. Findlay (personal communication, 1944) states that the mortality rate for the whole West African Command over a period of three years was 28.8%. We are indebted to him for permission to give this figure.

Haemolysis

In subtertian malaria a haemolytic anaemia occurs, but the reticulo-endothelial system is capable of dealing with the liberated haemoglobin, transforming it into haemosiderin and bilirubin, and only in the severer cases can free haemoglobin be demonstrated in the plasma (Stitt, 1942). In blackwater fever, however, the haemolysis occurs with such explosive suddenness that the renal threshold for haemoglobin is exceeded and this pigment appears in the urine. The cause of this sudden haemolysis is still unknown. The mystery is further increased when it is considered that severe cases of subtertian malaria, in which there is a profound anaemia and in which a large percentage of the circulating red cells may be parasitized, are quite common; and yet this is not the type of case which develops blackwater fever. Preceding and during the disease parasites are scanty in the peripheral circulation, often entirely disappearing early in the illness.

TABLE II.—*Details of Cases*

Case	Parasites in Blood	Red Cell Count and Hb %	Urine			Blood Urea Mg. per 100 c.cm.	Blood Transfusions	Intravenous Fluids	Remarks
			Hb Pig.	Alb.	Casts				
I	Scanty (1)	4,140,000 Hb 82 (4) 5,060,000 Hb 100 (8)	+ (1–2)	+ (1–2)	+ (1)	95 (4) 70 (7) 27 (13)	None	None	Mild case. No jaundice or vomiting
II	Absent	3,670,000 Hb 72 (2) 3,080,000 Hb 56 (4) 3,720,000 Hb 55 (6)	+ (1–2)	+ (1)	None	25 (3) 20 (4)	None	Sod. bic. soln. 30 oz.; N. saline 20 oz.	Moderately severe case. Slight jaundice; no vomiting
III	Absent	4,750,000 Hb 90 (2) 3,150,000 Hb 53 (4) 1,320,000 Hb 30 (9) 2,200,000 Hb 36 (11) 4,540,000 Hb 72 (29)	+ (1–5)	+ (1–8)	+ (4–11)	25 (2) 30 (5)	1 pint* (4) 12 oz.* (5) 15 c.cm.* (9) 1 pint (10)	Plasma 14 oz.; sod. bic. soln. 5 pints; glucose-sal. 6 pints	Severe case. Jaundice; vomiting; spleen palpable; loin pains
IV	Absent	4,210,000 Hb 80 (1) 3,280,000 Hb 60 (3) 3,900,000 Hb 60 (6)	+ (1–3)	+ (1–3)	+ (1–2)	45 (2) 30 (5)	None	Sod. bic. soln. 60 oz.; glucose-saline 20 oz.	Moderately severe case. Slight jaundice; vomiting; loin pains
V	Absent	3,200,000 Hb 63 (1) 3,140,000 Hb 62 (3)	+ (1–3)	+ (1–3)	None	37 (2) 30 (6)	None	Sod. bic. soln. 40 oz.; plasma 20 oz.	Moderately severe case. Slight jaundice; vomiting; spleen palpable
VI	Scanty (2) (3)	3,820,000 Hb 80 (1) 930,000 Hb 18 (5) 800,000 Hb 20 (7) 1,600,000 Hb 43 (10) 2,500,000 Hb 56 (35)	+ (1–3)	+ (1–15)	+ (1–13)	45 (3) 135 (6) 185 (11) 30 (35)	20 oz.* (5) 20 oz. (7) 40 oz. (8) 12 oz.* (11)	Sod. bic. soln. 67 oz.; glucose-sal. 40 oz.; sod. lact. soln. 40 c.cm.	Very severe case. Marked jaundice; severe vomiting; persistent hiccup; anuria 6th–7th day lasting 22 hours
VII	Absent	1,050,000 Hb 28 (2) 2,100,000 Hb 50 (4) 2,900,000 Hb 50 (7) 4,000,000 Hb 77 (15)	+ (1–4)	+ (1–7)	+ (4–5)	40 (3) 26 (5)	20 oz. (2) 20 oz. (3)	Sod. bic. soln. 60 oz.; glucose-saline 8 oz.	Severe case. Jaundice; vomiting; loin pains

Figures in brackets = days of disease. * Transfusion reaction.

For nearly a hundred years quinine has been considered a precipitating factor, and recently Cust (1943), Frewen (1943), and others have reported cases arising during quinine therapy, while Foy and Kondi (1938) state that the relation of the last dose of quinine to the onset of blackwater fever is so significant as to be more than casual. Fairley and Murgatroyd (1940) describe a patient with blackwater fever in whom four recurrent attacks of haemoglobinuria occurred, each precipitated by quinine. The relationship of the haemoglobinuria to the taking of quinine has already been mentioned in our cases. Yet the disease has occurred during treatment with mepacrine or pamaquin and in patients who have never received any quinine at all. In Case I haemoglobinuria returned after mepacrine treatment had inadvertently been started on the second day of the illness and disappeared as soon as the drug was discontinued. The part played by quinine in the aetiology is, of course, obscured by the fact that most patients with malaria are treated with this drug. In this connexion the statement by Findlay (personal communication, 1944), that the incidence of blackwater fever in the West African Command has considerably diminished since the substitution of mepacrine for quinine as a suppressive and as the therapeutic drug for uncomplicated malaria, is of great significance.

Other theories may be briefly discussed. Smith and Evans (1943) attempted to prove that the haemolysis is due to increased fragility of the red cells consequent upon lowering of the *p*H of the blood, but apparently made no actual observations in blackwater fever. They based their conclusions upon *in vitro* experiments with red cells suspended in saline buffered to different *p*H levels. Of more significance is the work of Maegraith, Findlay, and Martin (1943), who showed that normal human serum inhibited the haemolytic action of animal tissue upon homologous red cells. This antihaemolytic effect was reduced in sera from cases of blackwater fever, especially during haemolytic crises, suggesting that the haemolysis is due to a lack of an antilytic substance rather than to the presence of a lysin. This would appear to be a promising line of investigation. Fernán-Núñez (1936) thinks blackwater fever is an allergic reaction to the malaria parasite protein, and claims that persons liable to the disease show a positive reaction to the intradermal injection of non-infective suspensions of *P. falciparum.*

Cold seems to be a precipitating cause (Case III). There is here an analogy with paroxysmal haemoglobinuria, but in blackwater fever the Donath-Landsteiner reaction is negative.

The Anuria

Amongst other lesions the kidneys show blood-pigment casts in the tubules that are generally thought to be composed of acid haematin. Yorke and Nauss (1911) were able to produce renal obstruction by injection of haemoglobin into animals provided they were kept on a dry diet. They considered the obstruction was due to precipitation of acid haematin in the tubules from a concentrated urine. Baker and Dodds (1925), from similar experiments, considered that whether obstruction developed or not depended on the reaction of the urine. Obstruction occurred if this was acid but not if alkaline. Treatment of blackwater fever with alkalis, in an attempt to prevent anuria, became almost universal as a result of these experiments. Foy *et al.* (1943), in a review of the problem, point out that anuria in blackwater fever may develop in patients who have had a small haemolysis and who pass alkaline urine and, conversely, may not occur after a large haemolysis when the urine is acid. They also state that anuria is no less common since the introduction of alkali treatment. Maegraith and Havard (1944) share this view and emphasize the dangers of indiscriminate alkali therapy. Bywaters and Dible (1942, 1943), however, state that the renal lesions in cases of mismatched blood transfusion, crush syndrome, paralytic myohaemoglobinuria, and blackwater fever are very similar. In all these conditions pigment casts occur in the tubules, and although these observers do not consider they are the chief cause of the anuria, their cases of crush syndrome apparently benefited by alkali therapy. In addition to the pigment casts there is a catarrh of the whole nephron, falling with especial severity on the ascending loop of Henle and the second convoluted tubule. They point out that it is in these portions of the tubules that acidification of the urine probably occurs, and that the selective damage to these structures which can be produced by the injection of uric acid and acid sodium phosphate into animals has been attributed to this. They consider that the anuria in the above conditions is chiefly due to reabsorption of glomerular filtrate into the blood stream through damaged tubules. Maegraith and Havard (1944) state that the greatest damage in blackwater fever is in the distal convoluted tubule. As in blackwater fever an acidosis is usually present, the urine is highly acid, and the alkali reserve is lowered, there would appear to be a good argument in favour of alkali treatment. Those who state that it is of little value do not indicate whether this is still true if it is used early in the disease. We consider it should be used as early as possible—in fact, the urine of all our cases of malaria was kept alkaline as a routine. Thus Cases II, IV, and V had alkaline urine before the onset of the haemoglobinuria. In only Case VI did anuria develop, and then for a relatively short period. With care there is little danger of alkalosis, but alkalis should be stopped or be used sparingly if anuria or oliguria occurs, for there is then a danger of alkalosis even if the urine is still acid.

It should be emphasized that dehydration from excessive vomiting and sweating is probably an important factor in the production of anuria and oliguria in many cases. In Case VI, for instance, vomiting was unusually prolonged and severe. Loss of chloride in vomitus and sweat will, moreover, augment the danger of alkalosis from indiscriminate alkali therapy and will also increase the tendency to nitrogen retention. We thus consider that an ample fluid intake by oral and intravenous routes is just as important as alkali therapy, and, in addition to alkaline solutions, we used glucose-saline or normal saline to replace chloride loss (Table II). In all our patients save Case VI urinary excretion was kept abundant throughout the course of the illness by these means.

Treatment

The general treatment consists largely in skilled nursing, which in no other disease is of greater importance. The patient is often in a condition resembling shock, and death from circulatory failure is therefore a danger. Complete rest on a low pillow is necessary and the patient is forbidden to sit up or feed himself. In West Africa, cases diagnosed in units, unless close to the hospital, were not moved, but were treated in their own lines by a mobile medical team based on the hospital. A full description has been given of these teams by Findlay (1943). Large quantities of water and fruit juice with glucose should be given, and all other food except small amounts of milk or junket withheld until acute symptoms have subsided. The daily fluid intake by the mouth should be at least 8 pints. Proteins should be restricted until well into convalescence. Fluid intake and output charts should be kept. Individual symptoms such as vomiting, hiccup, and hyperpyrexia must be treated as they arise. In Case VI all attempts to arrest the distressing hiccup, including cocaine by the mouth, failed. For severe loin pains, atropine 1/200 gr. was of value in Case VII. Oxygen, nikethamide (coramine), adrenaline, and bed blocks must be available for circulatory failure. It is useful to keep successive samples of urine in test-tubes so that the reaction and the degree of pigmentation can be easily observed, while a red cell count and a haemoglobin estimation should be undertaken daily.

Blood Transfusion

This is necessary if a dangerous degree of anaemia develops after massive haemolysis, but considerable judgment must be exercised in individual cases in deciding when to transfuse. Blood should never be given if oliguria is present. It is stated that in blackwater fever the donor's cells are liable to haemolysis as well as those of the recipient. Consequently, cross-grouping is always necessary. In spite of this precaution two of our cases had severe reactions (Table II). In Case III attempts at transfusion were persisted in; the fourth, which was uneventful, undoubtedly saved the patient's life. This transfusion was given very slowly, a pint being administered in 4½ hours. In Case VI the first transfusion was continued in spite of a rigor, as the patient was moribund. The anuria which followed this was possibly precipitated by it. The absence of reactions and the non-appearance of haemoglobinuria during subsequent transfusions in this patient suggest that the failure of these to raise the red cell count was at least as much due to the normal haemolytic process of the disease as to haemolysis induced by the transfused blood. In Case VII we transfused early on the second day of the disease while haemoglobinuria was still present. One pint was given at the rate of 8 drops to the minute, being preceded and followed by one pint of 2% sodium bicarbonate solution. A similar procedure was carried out the next day, 10 oz. of blood being followed by one pint of sodium bicarbonate solution and then by a further 10 oz. of blood. In this patient, a rise of one million red cells per c.mm. was obtained in 48 hours in spite of continued haemolysis, and no reactions were observed. This method would appear worthy of further trial.

Prevention of Anuria

On diagnosis an intravenous drip of 2% sodium bicarbonate was set up immediately, 1 to 2 pints being administered fairly slowly—i.e., 1 drop every 2 seconds. A rate of three pints in 24 hours was never exceeded, but recourse was had to intravenous saline, saline-glucose, or plasma to keep the excretion of urine abundant and to replace chloride loss. At the same time, sodium bicarbonate 1 dr. four-hourly was given by mouth and as much bland fluid as the patient could be made to take. In the Tropics a urinary output of from one-half to two-thirds of the intake appears to be satisfactory in blackwater fever. In Case VI the injection of 20 c.cm. of a mixture of equal parts of saturated sodium bicarbonate and 3-mol. sodium lactate was tried, as recommended by Findlay (1942), because difficulty was experienced in maintaining alkalinity of the urine. This was without effect, probably because the kidneys were failing. The first specimens of urine passed after 22 hours' anuria were still acid. Possibly alkalis were pushed too hard in this case, but they nevertheless seemed to do no harm. This patient was, in any event, desperately ill. The treatment of established anuria consists in the application of heat to the loins, and dry cupping may be tried. In Case VI this was apparently successful. As already stated, alkalis should be discontinued.

In order to treat the accompanying malaria, a course of mepacrine, starting in small doses—e.g., 0.1 g. daily, gradually increasing to 0.3 g. daily—should be given during convalescence. It is probably best to give mepacrine even if no parasites are present in blood films—which is usually the case—as otherwise a malarial relapse may occur. Anaemia should be treated by good food and large doses of iron.

Summary

Seven cases of blackwater fever in British Service personnel in the West African Command are described.

The relationship of the disease to subtertian malaria and the mechanism of the haemolysis and the anuria are discussed. Special reference is made to treatment with blood transfusion, alkalis, and a large fluid intake. Evidence is produced to show that alkalis are probably of value in preventing anuria.

For permission to publish these cases we wish to thank Brig. G. M. Findlay, C.B.E., Consultant in Medicine, West African Command: Brig. R. A. Hepple, O.B.E., *M.C.*, then D.D.M.S.; and our late commanding officers, Col. L. A. Harwood, T.D., and Col. W. H. McKim McCullagh, D.S.O., *M.C.* (later A.D.M.S.).

DIAGNOSIS OF MALARIA IN WEST AFRICA

BY

D. G. FERRIMAN, D.M., M.R.C.P.

Squad. Ldr., R.A.F.V.R.

This paper is based upon experience of over 2,000 cases of malaria in white personnel at an R.A.F. hospital in West Africa. The type was almost exclusively malignant tertian. The vast majority of patients had not been exposed to infection prior to service in West Africa, and their stay was comparatively short. Drug suppression and antimalarial discipline were in force. Owing to a big drainage scheme and efficient screening, the infection rate, though not low, was less than in many places on the coast. Patients were nearly always admitted to hospital in an early stage of the disease. Pernicious cases were uncommon; only 9 of blackwater fever, 4 of cerebral malaria, and 1 of the choleraic type were seen, all of which recovered. No algid case presented. Chronic malaria was very uncommon; not more than 6 cases were seen.

M.T. malaria closely mimics many diseases; it is dangerous, and parasites are not always found in the blood. Treatment, therefore, often has to be on suspicion. However, it is possible to become a little obsessed with the diagnosis when malaria accounts for no less than two-thirds of medical admissions—with results which are not always happy. The following is an account of matters found helpful in diagnosis. Cases of malaria will be referred to as proved (or slide-positive) and clinical (or slide-negative), depending upon whether parasites were or were not found in the blood stream. Diagnosis was often helped by a short period of observation. Grave complications, however, are so liable to arise in seriously ill cases of malaria that treatment was not delayed in any serious febrile illness unless the clinical picture pointed definitely to a non-malarial disease. For routine purposes a temperature of 103° was taken as an objective dividing-line between seriously and not so seriously ill cases; these will be referred to as high- and low-fever cases respectively. In the great majority of low-fever cases it was found possible to reach a shrewd diagnosis within 48 hours; for the remainder, a working rule was adopted that antimalarial treatment should be tried when doubt still existed at the end of 4 days.

Pathological Diagnosis

Antimalarial therapy was started on finding a positive blood slide. Slides were taken on admission, before starting treatment, in all cases. The following trial was made to determine the optimal delay for blood slides in low-fever cases. Treatment was withheld in 136 virtually consecutive low-fever cases of suspected malaria—indefinitely in the first 71, and then for four days in 65. Blood slides were taken on admission, and night and morning. Ninety cases revealed parasites—66 in the first slide, 14 more within 24 hours, and 6 more within 48 hours; only 4 showed parasites at longer intervals. It was concluded that delay beyond 48 hours for this purpose was of little value. The figures are very similar to those in a series of 968 reported by Hughes and Bomford (1944) from another West African Service hospital. Slides were taken night and morning for 48 hours in high-fever cases even though treatment had been started, since it was found that parasites still appeared in an appreciable number of cases. In B.T. malaria parasites are most easily found on the rise of temperature in each rigor. Such typical rises are not common in M.T. malaria. Slides were taken in those which did occur, but parasites were by no means always found. Suppressive therapy was stopped while diagnosis was under consideration. It was started again as soon as malaria was thought excluded (i.e., a maximum suspension of 4 days).

Malaria parasites are harboured somewhere after an attack, possibly in the bone marrow. Until it is known that they cannot be found in the marrows of parasitized but symptom-free men a positive marrow smear cannot be accepted as diagnostic of active disease. Even were this the case, the number of blood-slide-negative cases of suspected malaria was far too great to justify the routine use of sternal puncture in West Africa. It was tried in a few such cases out of scientific interest, and parasites were sometimes seen.

Clinical Diagnosis

A number of clinical features were believed to assist in diagnosis. Splenomegaly was a very strong pointer. Other causes were rare. Admittedly 5% of 219 cases on the station had splenomegaly, and could be admitted with non-malarial illnesses, but this would hardly have accounted for more than 1 to 2% of admissions. The percentage, however, in febrile cases admitted to the medical wards was very much higher—approximately 25% of 406 consecutive cases. Tenderness of the spleen was virtually pathognomonic, and definite tenderness under the left costal margin, in the absence of a palpable spleen, came to be regarded as of great diagnostic value.

The anomalous behaviour of many cases of malaria superficially resembling other diseases was very helpful. Deterioration was of great assistance; the common non-malarial illnesses concerned in differential diagnosis (febrile catarrhs, simple enteritis, and dysentery) tended to recovery, and that fairly rapidly. Another valuable pointer was in the time relations between constitutional and local symptoms. In the usual non-malarial illnesses the onset might be with constitutional symptoms only, but local ones soon followed which persisted after disappearance of the former. In enteritis, for example, onset might be with 12 to 24 hours' headache, but the subsequent diarrhoea outlasted the headache by several days. In malaria, constitutional symptoms often preceded the local ones by days or persisted after their disappearance. The typical tertian periodicity of fever and symptoms was helpful when met, but unfortunately was not particularly common. Incidentally actual rigor was very uncommon and usually heralded blackwater fever. The combination of the symptoms of two non-malarial diseases, such as coryza and diarrhoea, was felt to indicate malaria. Two other points were of limited value. The degree of constitutional disturbance and the duration of illness might be incompatible with the non-malarial disease concerned. Thus a case with severe headache, a temperature of 105°, and coryza was hardly likely to be a febrile catarrh; such obvious cases were, however, exceptional.

The likelihood of malaria varied considerably between the various presenting symptom-complexes, and this was of much help in diagnosis. Very many cases presented with symptoms and signs of a general nature only. These included headache, backache, aching limbs, dry cough, vomiting, fever, splenomegaly, and herpes. They will be called constitutional cases. It was believed that all such cases should be regarded as malarial, positive slides or not, unless definite reasons appeared to the contrary. They were indistinguishable from proved cases. No common satisfactory alternatives existed; some form of heat exhaustion or an unknown virus was a possible cause, but little or no evidence existed for either. A number got worse or failed to recover until given antimalarial therapy. Others apparently recovered without, but of these an undue proportion returned shortly after discharge in frank attacks of malaria; splenomegaly was seen to subside without treatment in a case or two of this type. Constitutional symptoms might usher in many diseases which later declared themselves by local symptoms; such possibilities had to be excluded by a short period of observation.

An analysis of the symptom-complexes in 345 consecutive cases of proved malaria was rather instructive. Results (to the nearest 0.25%) are given in Table I. Four symptom-complexes accounted for 97.75% of cases. Constitutional symptoms only were found in the great majority. It was considered simply a coincidence that while coryza and productive cough and simple diarrhoea were the only other common symptoms, febrile catarrhs and a simple enteritis were the commonest diseases after malaria. Dysentery was found in only a handful of cases. Other syndromes occurred involving differential diagnosis from such diseases as pleurisy, acute rheumatism, appendicitis, cystitis, amoebic hepatitis, and conditions leading to coma. All these were uncommon, none occurring more frequently than 0.25%. It was obvious that while malaria *might* present in

TABLE I

1. Constitutional group (dry cough in 25%)	83·25%
2. Coryza or productive cough	9·25%
3. Simple diarrhoea	4·5%
4. Dysentery	0·75%

many guises its common forms were few. The analysis is very similar to a larger series (846) reported by Hughes and Bomford (1944).

A mildly statistical inquiry showed the proportion of all cases with coryza and productive cough, simple diarrhoea, and dysentery which were due to malaria.

The total number of cases and the numbers yielding positive blood slides, with these symptoms, were collected for some months. The next step was to estimate the cases of clinical malaria in each group. These estimates were obtained in the following manner. First, it was assumed that all cases with constitutional symptoms only were cases of malaria (unless definite evidence had shown to the contrary). The total numbers and the number with positive slides in this group had been collected over the same period; the proportion of proved to clinical cases was noted. It was then assumed that this proportion remained the same in cases of malaria with any other symptom-complex. Figures for the cases of clinical malaria in each group could thereby be obtained from the known number with positive slides; the proportion of cases due to malaria either in the whole group or in those with negative slides could then be calculated. The results are given in Table II. The proportions were worked out separately for high- and low-fever cases. Similar calculations were made for cases of follicular tonsillitis to determine the frequency with which the activation of latent malaria by a non-malarial illness might be expected in this neighbourhood. For obvious reasons, the results can only be taken as rough guides. Sampling errors may be present in the smaller groups. The second assumption may be erroneous. Correction of the possible error in the first assumption (namely, that some slide-negative constitutional cases were not due to malaria) would, however, strengthen most of the conclusions which were drawn. Nevertheless some results were highly suggestive.

TABLE II.—*Estimated Proportion of Cases with Respiratory Symptoms, Simple Diarrhoea, and Dysentery, due to Malaria, and of Follicular Tonsillitis complicated by Malaria*

Symptom-Complex	Total Cases	No. with Positive Slides	Percentage of Cases due to Malaria	
			Whole Group	Negative Slides
Constitutional high fever	172	145	6 out of 7 gave positive slides	
Constitutional low fever	315	168	Every other case gave positive slides	
Coryza or productive-cough high fever	23	13	65	21·5
Coryza or productive-cough low fever	120	21	35	21
Simple-diarrhoea high fever ..	20	10	57·5	16·5
Simple-diarrhoea low fever	119	11	18·5	10
Dysentery high fever	19	4	25	4·5
Dysentery low fever	63	1	3	1·5
Follicular-tonsillitis high fever ..	14	2	16·5	3
Follicular-tonsillitis low fever ..	33	—	++ against (none with positive slides)	

The following conclusions were drawn. Positive slides could be expected in most high-fever cases of malaria, but probably with much less frequency in low-fever cases. The activation of a latent malaria by a non-malarial illness was uncommon in the area. Cases with dysentery and negative slides were most unlikely to be caused by malaria. Cases with simple diarrhoea, low fever, and negative slides were unlikely to be so caused. On the other hand, malaria was a not uncommon cause in cases with coryza and productive cough, or of simple diarrhoea with high fever.

A therapeutic trial produced results of interest.

All cases in the groups with low fever and constitutional symptoms, coryza or productive cough, or simple diarrhoea were observed without treatment unless (*a*) slides became positive, (*b*) the temperature rose above 103°, or (*c*) they had failed to recover after 5 or 6 days. Those recovering fully were discharged without treatment. Twenty-four of the constitutional and 70 of the other two groups were re-examined at the end of three months. Three of the 24 but only 1 of the 70 had returned in frank attacks of malaria; in all 4 instances return was within one month of discharge. The incidence of such return was thus 9 times as great in the constitutional group as in the others. Incidentally, 2 of the respiratory and diarrhoeal groups had developed subclinical malaria (see later); nothing that was remotely suggestive of chronic malaria had developed in any.

The importance of malaria as a cause in the constitutional group of cases received confirmation. Unfortunate sequelae in the respiratory and diarrhoeal groups were most uncommon, though with the methods used in the trial a number of cases of malaria were undoubtedly discharged without treatment. It was concluded that if after more careful exclusion of malaria a case appeared to be one of febrile catarrh or simple enteritis it could safely be treated as such. The matter was not entirely academic, as much working time could be saved by accurate diagnosis.

Subclinical Malaria

This term was applied to a condition seen in ambulant personnel. The main complaint was of recurrent headache. Backache, aching limbs, and malaise occurred; the sense of well-being which followed treatment was a notable feature. Splenomegaly was present in about one-third of cases. Slight pyrexia probably occurred. The general condition was good and anaemia absent. Blood slides were usually, though not invariably, negative. The incidence was estimated at about 10% of men on the station. Response to antimalarial treatment was good. The absence of anaemia and the condition of the patients excluded the diagnosis of chronic malaria as usually accepted. Latent malaria suggests a symptomless parasitization. The term "subclinical malaria" was preferred to "incompletely suppressed malaria," which it was felt laid too much emphasis on control of infection by suppressive therapy, as opposed to that by natural immunity processes.

Its existence was inquired for as a routine in all cases admitted to the medical wards and, if found, led to a course of treatment before discharge. When doubt existed as to diagnosis, its presence was thought to favour malaria.

Affected ambulant personnel were treated by an increase in suppressive therapy.

Details of the clinical data upon which this account of "subclinical malaria" was founded will now be given. A number of these cases were seen, but only 61 were observed closely enough for their records to be worthy of analysis. 41 had had headaches more frequently than once a week, and were under observation for at least one month before and one month after treatment. Ten had had headaches between once a week and once a fortnight, and were observed at least two months before and two months after treatment. Relief was judged to have taken place in the first group if headaches occurred less than once a fortnight, but in the second group only if headaches had disappeared altogether. These 51 cases were given the ordinary hospital course of treatment. Seven of them relapsed after several months, and these and 10 others were placed upon increased suppressive therapy as out-patients. Periods of observation and criteria of relief remained the same. The results are given in Table III.

TABLE III.—*Results of Treatment in Subclinical Malaria*

	Total Cases	Relieved	Definite Improvement	Relief or Improvement	Little or No Improvement
Hospital treatment ..	51	32	13	45	6
Increased suppressive therapy	17	10	4	14	3

A Note on Treatment

Treatment was given as a routine for twice as long as it took for the temperature to fall to normal, with a minimum of 7 days. Mepacrine was administered from the start, 0.1 g. t.d.s. for a maximum of ten days. If longer courses were needed, quinine 10 gr. b.d. replaced mepacrine. Quinine 10 gr. t.d.s. was given in addition for the first 2 to 3 days for the sake of its better initial control. A five-day course was employed for cases considered likely to recover spontaneously. This short course was used in the hospital treatment of subclinical malaria. Routine suppressive therapy consisted of 0.2 g. mepacrine twice a week. In the ambulant treatment of subclinical malaria 0.1 g. mepacrine and 5 gr. quinine were given daily for two weeks; 0.1 g. mepacrine was then given 6 days a week, either temporarily or permanently. This flexible scheme of treatment was considered preferable to one in which a standard course was used for all cases. Such a course would have had to be a long one to cover the more serious cases, and the loss of working time would have been very considerable. Results seemed satisfactory.

Summary

An account is given of clinical and pathological points found helpful in the diagnosis of M.T. malaria. A condition occurring

in ambulant personnel is described, for which the term "subclinical malaria" is proposed. Specific treatment is also briefly described.

I have much pleasure in thanking the Director-General of the Royal Air Force Medical Service for permission to publish this paper. I am deeply indebted to many for help in the work. In particular I wish to thank Wing. Cmdr. W. P. Stamm for numerous useful suggestions, Fl. Lieut. R. D. Tonkin for assistance in the wards, Squad. Ldrs. R. J. O'Connor and M. Nelson and their able technicians for examining thousands of slides, and Sister M. Giles for suggestions about treatment. Finally a special word of thanks to Dr. Greer of the Colonial Service for constant advice and support.

REMOVAL OF PROJECTILE FRAGMENTS AND IMMOBILIZATION OF WOUNDS IN FORWARD AREAS

BY

JAMES A. ROSS, F.R.C.S.Ed.
Major, R.A.M.C.

Trueta has applied John Hilton's principle of rest to the treatment of war wounds, through the agency of the plaster cast. This factor, immobilization, and another one in the attainment of rest in wounds in forward areas—the removal of the causal projectile foreign body—form the subject of this paper.

The Projectile Foreign Body

Trueta (1944) quotes Friedrich as aiming at complete excision of wounds, removing bacteria by excising the contaminated tissues in a single mass, like a malignant ulcer. Even those who attempt to carry out this aim most faithfully (Yudin, 1943) cannot do so in most instances without imperilling vital structures. Trimming and laying open for drainage is the best that can be done in the vast majority of cases. Incidental to this is the removal of projectile fragments. "The length and direction of a penetrating wound are unknown till the projectile has been located, nor has the tract been laid open throughout its extent till it has been removed" (*Lancet*, 1944). The attempt to remove the foreign bodies which act as guides to those "very complicated cavities," wound tracts, will help to establish the true nature of the wound (revealing, for example, a severed nerve, a torn joint synovial membrane, or a crack fracture), hitherto unsuspected.

"Time spent on reconnaissance" by x rays is "seldom wasted." "A forward operating centre without an x-ray unit is incompletely equipped, and only under exceptional circumstances can the omission of this important accessory service be justified" (*Lancet*, 1944). The passage of shell or mortar fragments often opens areolar planes, splitting fascia longitudinally, which closes behind them. This split may well be missed in the initial operation on the wound, and unless skiagrams are taken the presence of the foreign body may not be suspected. Fatty areolar tissue, moreover, opens before the entering projectile fragments and closes behind them as if never penetrated, and the fasciculi of coarse fibres of the deltoid and gluteal muscles rearrange themselves after the passage of a projectile, rending a "blind" search uncertain of success. No surgeon can write complacently "Wound excised" on the patient's card unless he has had the patient x-rayed and the causal projectile demonstrated and removed. A blister or discoloured patch in the skin often acts as a guide for subcutaneous projectile fragments, and an incision there will reveal the foreign body and drain the wound tract. But deeper fragments have no such stigmata, and skiagrams are necessary. In the field the time required for accurate location as in hospitals at the base may not be possible. But views in two planes can always be taken, giving a sufficient guide.

A recent tragic case illustrates the complications that may ensue through leaving projectile fragments *in situ*.

Case History.—A C.C.S. orderly, wounded on March 17, 1944, in the C.C.S., was taken to the theatre two hours after wounding. He was found to have a shell wound at the outer aspect of the left thigh, through the superficial fibres of the vastus lateralis. Tl wound was considered tangential, and layer by layer its edges we trimmed and then left open. Routine sulphanilamide powde vaselined gauze, and a light plaster-of-Paris bandage were applie He was evacuated on March 19 in fair condition; no undue pa had been complained of. Lieut.-Col. W. M. Capper, O.C., surgic division of a general hospital, has supplied the further histor "Admitted March 20, 1944, obviously ill and in pain. Pulse 14 Left leg tender and swollen; dark-brown oedema extending up thig and over abdominal wall almost to umbilicus, and present i popliteal space also. Plaster removed. Local wound clean and n tender." After blood transfusion: "Operation. Wound explore locally and found to pass across thigh. There was escape of co siderable amount of gas. . . . A large F.B. (about 2 in. by 1 in was found in an abscess cavity behind the femoral vessels. P and anaerobic oedema had tracked up and down the femoral sheat and it was therefore present in the upper thigh and in the poplite space; sartorius, rectus femoris, and vastus externus were excise and part of the adductor magnus; he was too ill for amputatio In spite of parenteral sodium penicillin in large doses and A.G.C serum, the patient died on March 21."

The foreign body was unfortunately missed at the primary oper tion. Even in a wound considered merely tangential, a skiagra should have been taken. The attempt to remove the F.B., guide by the skiagrams—antero-posterior and lateral views—would ha opened the tract and given the required drainage in an are peculiarly liable to anaerobic infection.

In treating abdominal wounds the actual foreign body often ignored. "The discovery of foreign bodies in the cases is of little importance. They may be difficult to loca in the posterior abdominal wall, and time spent in searchi for them is wasted. They may also be difficult to distingui from fragments of bone where part of the spine or pelvic gird has been fractured in the tract" (Blackburn, 1944). But i the abdominal cavity, where vital structures are involved, t role of the foreign body, acting as a signpost directing the trac of the wound, is most important. If the attempt to see t foreign body and actually feel it in the open wound is n considered essential, the preliminary view of its shadow o an x-ray plate is most valuable. It gives a clue to the probabl viscera injured, and a guide to the position of the incision i the abdominal parietes.

In one campaign criteria for the removal of foreign bodi were when they were provoking pain, causing pressure o important structures, or aggravating sepsis (Mason Brow Dennison, Ross, and Divine, 1940). Sooner or later t majority—H.E. shell fragments, mortar, bomb, or grenade fra ments, pieces of projectiles from long-range artillery such "Anzio Annies and Archies"—give rise to trouble. The press on nerves and erode blood vessels. The poisonous natu of certain projectiles, moreover, must be remembered. Blaxlan (1942) describes a case of fatal phosphorus poisoning from bullet.

If embedded near sphincters or in joints the constant mov ment in these places greatly reduces the chance of the forei body being walled off by fibrosis. Not being walled off, t foreign body will act as a continual source of irritation a delay healing. At all times they are a potential source sepsis liable to acute exacerbation. Though the "primary metallic foreign bodies themselves may be sterile owing their heat (and the familiar blister in the skin overlying t fragment that has not quite perforated testifies to this freque high temperature), the "secondary" foreign bodies they car in—mud; bits of equipment—are teeming with organism "Many of the most serious complications of infection, pa ticularly secondary haemorrhage, can be traced to retain foreign bodies and the contaminated clothing around them (Donald, 1944). The search for the metallic foreign bodi visible in the skiagram will help to find these non-opaq "secondary missiles, such as clothing" (Law, 1944).

A prolonged hunt for foreign bodies in shocked patients unjustifiable, and the field surgeon leaves those in certain are —i.e., the thorax and the head—to his colleagues with speci facilities at their own centres. But in the general toilet wounds as many as possible must be removed. The sear is also advisable for psychological reasons, for patients inva ably want to know if the bullet has been removed, and a for the gory relics as souvenirs: extracted shrapnel demo strates to the patient that his treatment has not been skimped.

In compound fractures the examining finger almost certainly will not be able to distinguish between projectile fragments and loose portions of bone, but, as such bony fragments require removal, nothing is lost by removing the loose hard lumps found in the depths of such wounds. Special instruments—e.g., Bergonié's electric vibrator, D. A. Willis forceps (Hamilton Bailey, 1942)—are not available or required in forward areas; a long pair of artery forceps or bullet forceps are sufficient.

Immobilization

Transportation of wounded is an administrative task. Field surgeons must assist this by making their patients fit for transportation. In the Middle East campaigns 1940-3 "travel over rough desert tracks was generally regarded as the most serious ordeal for the badly wounded man" (Wilson, 1944). Methods of immobilization had to be learnt that would stand up to the gruelling test of a long evacuation line. Once again, with recent Allied advances, the same rules apply. In the rows of patients laid on stretchers in the tents of a staging unit the faces of men correctly splinted contrast strongly with the apprehensive haggard appearance of those in whom a loosely fixed Cramer wire splint or an insufficient plaster slab has utterly failed to prevent every jolt and bump shaking up their wounds. "I had a stiff journey, sir, as it went bouncing up and down," is the usual expression of patients, pointing to an unsplinted limb. Careful plaster technique pays on the line of communication: firm, evenly applied plasters are far more comfortable than crumpled, cracked, and ragged-ended efforts.

All *flesh wounds* of any extent should be adequately protected. A penetrating wound over the scapular angles or the point of the heel will become the seat of cellulitis unless carefully padded. Wounds of the flank need covering by a plaster plaque—not merely a many-tailed bandage, which rucks up so easily. Penetrating wounds of the shin region treated without *x*-ray facilities should invariably be immobilized in a plaster. Cracks in the tibia occur very often with modern projectiles, and, if immobilized, many hours of misery are saved before reaching a centre where a skiagram puts the diagnosis beyond doubt. In addition, reactionary haemorrhage from the crural arteries is apt to occur in calf wounds if these are not immobilized in plaster casts. Light plaster casts are also advisable to protect amputation stumps on their journey down, and now plaster corsets are recommended for abdominal wounds (H. Rogers, 1944).

Gunshot wounds of the vertebrae should be immobilized in a padded posterior shell. With partial injuries of the spinal cord, and when the cauda equina is involved, any chance there may be of recovery when the patient reaches a neurosurgical centre is irrevocably lost if no attempt is made to prevent further damage to the nerve tissue by broken laminae, fragments and foreign bodies. The risk of pressure sores in a well-padded plaster shell is a minor matter compared with this much graver possibility. The plaster may be a dorsal shell, extending as far forwards as the anterior axillary line at the sides and including the legs and feet to prevent foot-drop, or a lesser shell fixing the trunk only, if there are no neurological signs. A fractured spinous process travels much better in a posterior shell than lying on a stretcher merely protected by cotton-wool. When complete paraplegia is present, however, rigid immobilization is not so necessary, because irremediable damage has occurred; still, such a case will travel better in a well-padded plaster shell.

Fractured pelvic bones should be similarly fixed; a few turns of elastoplast and a rolled-up blanket on each side are most inefficient immobilizing agents in such cases.

"A striking feature of war injuries is the preponderance of wounds of the extremities" (Trueta, 1944). "All forward surgeons must be orthopaedists up to a point" (Donald, 1944). Limb wounds should therefore receive as much attention as more spectacular abdominal injuries. In a C.C.S. recently, over a period of 4 months, in 687 patients with 873 lesions, 717 were limb wounds—i.e., 82%. In another 3-months period, in 204 patients with 299 lesions, 237 were limb wounds—i.e., 79%.

In *fractures of the acetabulum and upper third of the femur*, often with large gluteal wounds, the Thomas splint is unsatisfactory, and a Whitman plaster should be applied. Two standard methods for fractures of the shaft of the femur are fully described by Buxton (1942, 1943). The complete "Tobruk" plaster—i.e., enclosing the limb in a plaster case and then fixing this in a Thomas splint by further plaster bandages—gives the best immobilization in cases with gross comminution. The "double cuff" method—i.e., a cylinder of plaster-of-Paris round the limb and bars of the Thomas splint, incorporating the adhesive strapping extension already applied—gives adequate immobilization in most cases. Rotation of the limb outwards in this method is prevented by rolls of cotton-wool on each side of the limb between it and the Thomas splint bars underneath the plaster. Some prefer strapping applied to the unshaven skin for better traction; but as secondary suture at the base is favoured by a clean-shaven skin shaving is preferable. In the cuff method, moderate tension is maintained on the fracture by inserting the usual "Spanish windlass" stick between the tapes or cord leading from the extension strapping to the end of the splint. A fixed extension after the principle of one method used at orthopaedic centres (Charnley, 1944) is therefore obtained. If the tapes are carried round the side bars of the Thomas splint before knotting over the end of the splint the effect of extension is largely lost. The foot and heel are generally left out in this method except when foot-drop is present owing to sciatic-nerve injury. Meticulous attention must be applied to the sling under the heel; if carelessly applied, and twisted, a pressure sore will form in 24 hours. The Thomas splint, slightly bent at the knee, is preferable to the straight splint in those appliances, as the knee-joint is thus kept in the optimum position of slight flexion.

Compound fractures of the tibia are immobilized in an above-knee plaster. This, however, in itself is not enough Such plasters have the knee slightly flexed. A pillow or folded blanket is required under this bend to prevent the limb rolling outwards and the main weight being borne on the heel. Such a pillow or blanket often shifts, and the heavy, slightly angled plaster then lies loose on the stretcher. The patient invariably tries to twist himself over on one side to let the leg lie outwards, flat. With other wounds present as well, this may be difficult or impossible. In any case, the patient lies in an awkward strained position. The problem is solved by placing the limb encased in a plaster on a Thomas splint supported by the method L. S. Rogers (1943) devised. A foot-piece of a large size is taken and plastered firmly to the splint with the circle end downwards. A piece of Cramer wire 2 ft. long is plastered across the base as a horizontal rest. With this support, which is a self-contained apparatus, the patient can be moved from a stretcher to a bed without disturbing the position. The limb is elevated in this method; "I consider this precaution [elevation] of the utmost importance in preventing oedema and consequent constriction" (Trueta, 1944). The contraindication to this method is when grave vascular damage has occurred—i.e., when the posterior tibial artery has been involved. Such cases require the limb to be below the heart level, to conserve the blood supply.

All *penetrating or perforating wounds of the foot*, with compound fractures of tarsal and metatarsal bones and phalanges, should be immobilized in plaster casts. Wounds dressed merely with cotton-wool and gauze become painful: the foot swells and the patient tends to hold it in an equinus position unless immobilized. Sepsis also is rendered liable, in spite of penicillin and chemotherapy, and secondary suture at the base is jeopardized. This applies especially to wounds of the tarsal bones, so liable to osteomyelitis. 100% of compound fractures of the os calcis arriving in South Africa (D.M.S. Middle East, 1943) required amputation. The plaster boot stopping half-way up the leg is not sufficient; unless the cast is carried up over the curve of the calf muscles to the level of the tibial tubercle it is quite insecure. A Cramer wire splint is a most unsatisfactory immobilizing agent, except for the most temporary occasions. It is too apt to work loose, as it cannot be moulded accurately to the limb contours like a plaster.

Compound fractures of the scapula, clavicle, and humerus should be immobilized in a thoraco-brachial plaster. Flannel bandages are not sufficient; they have a great tendency to unwind in this position with restless patients. The application of this plaster cast has been greatly facilitated by Jack's (1943) contrivance. The axilla is well padded. The humerus itself is immobilized by a "plaster from the nape of the neck down over the elbow and up to the axilla" (Buxton, 1942) and approximated to the side. The elbow is fixed at a right-angle and the forearm brought across the front of the lower chest. The forearm is immobilized by an ulnar plaster gutter extending to the heads of the metacarpals, with fingers free for full movements. The whole, including the shoulder on the affected side, is incorporated in a circular plaster round trunk and limb. A patient thus fixed can travel comfortably, and is more portable than in the aeroplane-splint position, with shoulder abducted to 90°.

Wounds of the carpus and forearm require padded split plasters, immobilizing the joint above and below the site of the fracture; the metacarpo-phalangeal joints should remain free. Metacarpal fractures, if not fixed with a firm dorsal slab but merely by a gauze bandage, will invariably arrive at base with the hand in an acutely palmar-flexed position—the worst possible for rehabilitation if not corrected immediately.

Wounded joints also need immobilization. Several severe reactionary haemorrhages have been observed from the deltoid muscle in wounds of that muscle also involving the shoulder-joint that were not placed in a thoraco-brachial plaster. When a foreign body is present in a joint, failure to immobilize is inexcusable. All penetrating wounds of the knee-joint should have strapping extension applied and the limb put in a Thomas splint. Any case in which the knee-joint has been aspirated should be similarly treated: a perfunctory plaster slab or Cramer wire splint is inadequate, and indeed inhumane.

Elevation of the limb in plaster limits oedema and constriction; often simple elevation in itself is equivalent to the administration of a sedative for relief of pain. It is safe, in addition, to pad and split plasters. "Don't use unpadded plaster casts in the early stage of treatment; even if it is proposed to split the cast and to elevate it, don't use an unpadded cast" (McIndoe and Watson-Jones, 1944). This applies especially to wounds of the hands; the rapid and extensive swelling of the dorsal subaponeurotic space with injuries as well as in whitlows makes splitting of a plaster enclosing the hand imperative. The splitting means not merely a division of the plaster cast by a slender knife-cut and not a partial splitting leaving upper and lower ends of the cast intact, but freely opening the cut at least 1/4 in. to allow for expansion the whole way down. An unpadded, unsplit plaster, enclosing the toes and forefoot for injuries there, should never be used. It is similar to the old Scottish instrument of torture "the boot," and a patient in one suffers accordingly. Splitting of the plaster cast itself may not be sufficient. Circular gauze bandages underneath the plaster must be cut, for when caked with drying blood they form constriction bands like iron rings.

Lack of immobilization may mean an endeavour to maintain free finger, toe, and joint movements. It has been noted that excessive splinting has done much harm during the war, especially through its effect in causing stiffness of the joints of the hand (Ritchie Russell and Harrington, 1944). But pros and cons of early movement, particularly in the treatment of fractures, recently under discussion again (Burns and Young, 1944), are not the concern of the surgeon in forward areas. Without immobilization the more immediate risks of shock, haemorrhage, and grave infections are run. Firm immobilization must therefore be one of the most important tasks of the forward surgical team.

In conclusion, one criticism of the plaster cast must be remembered: "The early stages of gas gangrene are easily overlooked or discounted, and the risk is increased by the modern closed methods of treatment" (Osborn, 1943). In a recent series of 44 cases of gas gangrene, however (MacLennan, 1944), in no case was the onset attributed to too tight a plaster. Keeping the warning in mind, the use of the padded split plaster is safe and sound.

I am grateful to Brig. F. A. R. Stammers for his advice and discussion over many of the problems discussed above. I am also grateful to Lieut.-Col. D. M. Mitchell for permission to record the above observations; to Capt. R. W. Ross for many suggestions; and to Pte. J. H. Foulds, R.A.M.C., for his painstaking and accurate recording of the case histories on which the above opinions are based.

THE RISE IN INCIDENCE OF SCABIES IN A CLOSED COMMUNITY USING ORDINARY SOAP, AND ITS SUBSEQUENT FALL ON THE SUBSTITUTION OF 5% TETMOSOL SOAP

BY

W. BARTLEY

K. UNSWORTH,* B.V.Sc.

AND

R. M. GORDON, M.D., F.R.C.P.

In a series of previously published papers Davey, Gordon, and Unsworth (1944) have shown that soap impregnated with tetmosol (tetraethylthiuram monosulphide) to the extent of 5, 10, or 20% cures a high proportion of animals infected with mange due to *Notoëdres*. The same authors and their colleagues (Gordon, Davey, Unsworth, *et al.*, 1944) proved that soap similarly impregnated with 20% tetmosol cured 80% of established human cases of scabies due to *Sarcoptes scabiei*.

In addition to proving the curative value of tetmosol soap these authors made a much more important observation, in that they proved that tetmosol soap completely protected animals against the acquirement of scabies due to *Notoëdres*. This fact, considered in conjunction with the remarkable curative properties of tetmosol soap when employed in connexion with human cases of scabies, caused them to make the recommendation that this soap should be used in infected communities to prevent the spread of the disease. The idea of employing such a universally used substance as soap as a vehicle for the sarcopticide has obvious advantages, for, if it could be shown that it protected against scabies and that little risk of dermatitis attended its use, the soap could be issued to the population without the necessity for parades or any other medical supervision. This method would be not only of great value in wartime but of still greater value in post-war Europe, when dealing with crowds of homeless refugees. At our suggestion Dr. Kenneth Mellanby (1945) carried out a test of the prophylactic and curative value of 10% tetmosol soap in a mental hospital where scabies was endemic. Of 1,213 patients who acted as controls, 1.8% were infected at the start of the experiment, 2.1% after six weeks, and 3.5% after 11 weeks, a total of 24 new cases having occurred in the community. Seven hundred and five patients, of whom 13.2% were infected, had 10% tetmosol soap issued to them in place of ordinary soap; at the end of six weeks the percentage of infected had fallen to 1.3, and was found to be at the same level after a further five weeks. In contrast to those using non-medicated soap, not a single new case had occurred. As a result of his investigations Mellanby came to the conclusion that: "These experiments show that tetmosol soap can act as a very efficient means of controlling scabies. It not only prevents the disease from spreading but also cures the majority of those who use it for a few weeks. There seems no doubt that its general employment would rapidly eliminate scabies from a community."

---

* Working under a grant from Imperial Chemical (Pharmaceuticals) Ltd.

While Dr. Mellanby's experiment was in progress Gordon and Unsworth (1944) conducted a further series of experiments on the prophylactic value of tetmosol soap among animals exposed to *Notoëdres* infection, and showed that 5% tetmosol soap, when applied once daily in the form of a lather containing 0.9% tetraethylthiuram monosulphide (the concentration at which the drug would reach the skin in ordinary ablutions), completely protected rats against a moderate infection with *Notoëdres,* whereas 2% and 1% tetmosol soap, when used under similar conditions, protected only a proportion of the rats so exposed. As a result of these experiments they suggested that " 5 per cent. tetraethylthiuram-monosulphide when incorporated in soap represents the lowest concentration of the drug which is likely to confer complete protection from scabies when the impregnated soap is used once daily."

By the courtesy of Dr. Mellanby and the staff of the mental hospital concerned, we have been allowed to continue the scabies investigation, and below are given the results obtained from the use of 5% tetmosol soap.

The Test

A group of 400 patients who had previously formed part of Dr. Mellanby's control population of 1,213 were again examined by us seven weeks later, making a total observation period of 18 weeks without treatment. The patients were then re-examined after six weeks and after a further period of seven weeks. This group of 400 persons was therefore kept under observation for a total period of 31 weeks, during the last 13 of which they were using 5% tetmosol soap.

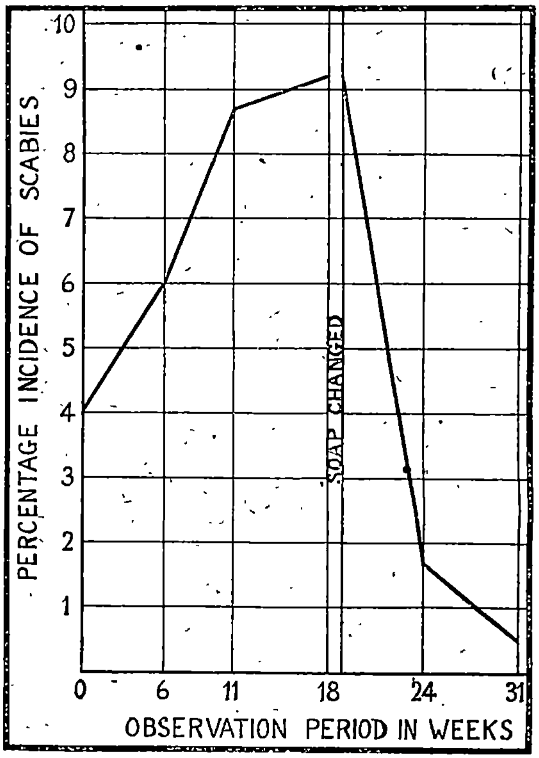
Before considering the results obtained by the use of 5% tetmosol soap in an infected community we wish to make one point clear. Examinations could be carried out only on the hands and arms and, in some doubtful cases, feet of the patients, a positive result being recorded only after a live mite had been demonstrated. Presumably owing to this partial method of examination a number of the cases recorded as negative were positive, although not on the hands and arms. This is shown by the fact that some cases without treatment were positive at one examination, negative at the next, and positive subsequently. It follows that the incidence of scabies on any date cannot be lower than that shown in the Table, but it may have been higher. It is important to note that our results with 5% tetmosol soap are directly comparable with those obtained by Mellanby (1945) when using the 10% strength, since the technique employed was the same.

The results obtained when using this method of examination on six occasions, conducted at intervals of approximately six weeks, are shown in the Table and in the Graph based on it.

Table showing Increase in Incidence of Scabies in a Closed Community at Various Intervals during a Period of 18 Weeks, and Therapeutic and Prophylactic Effects Following the Substitution of 5% Tetmosol Soap for Ordinary Soap

Soap	Time of Observation	No. of Weeks from Start	Total Persons Examined	No. Positive	% Positive	No. of New Cases During Each Period
Ordinary toilet	1st examination: 6–9/6/44	—	400	16	4	—
	2nd examination: 24/7/44	6	400	24	6	8
	3rd examination: 30/8/44	11	400	35	8·7	11
	4th examination: 19/10/44	18	400	37	9·2	2
Soap Changed						
Impregnated with 5% tetmosol	5th examination: 1/12/44	24	398	7	1·7	1
	6th examination: 22/1/45	31	392	2	0·5	0

It will be seen from the Table and the Graph that during the 18 weeks in which the community used ordinary soap the total number of cases of scabies rose from 16 (4%) to 37 (9.2%) and that 21 new cases were observed. During the subsequent 13 weeks, in which the community used 5% tetmosol soap, the number of cases fell from 37 (9.2%) to 2 (0.5%) and only one new case of infection was observed, this patient having contracted scabies some time during the first six weeks of using the impregnated soap.



Graph plotted from Table

Mellanby (1945), when recording the results of using 10% tetmosol soap in a community of 705 persons for 11 weeks, observed three cases of dermatitis, all of them among women. In the present series of observations 400 persons, all of them women, used 5% tetmosol soap for 31 weeks without any cases of dermatitis being observed.

Summary and Conclusions

The incidence of scabies in a closed community of 400 persons was observed over a period of 31 weeks, during the last 13 of which 5% tetmosol soap was substituted for ordinary toilet soap.

During the 18 weeks in which ordinary soap was used the incidence of scabies rose from 16 cases (4%) to 37 (9.2%) and 21 new cases of scabies were recorded. At the end of this period 5% tetmosol soap was substituted for ordinary soap, and during the remaining 13 weeks of observation the incidence of scabies fell from 37 cases (9.2%) to 2 (0.5%) and only one new case occurred. This case appeared during the first six weeks, no new case occurring during the last seven weeks of using the impregnated soap.

No cases of dermatitis were recorded among the 400 persons using 5% tetmosol soap for 13 weeks.

It is concluded that 5% tetmosol soap acts as a prophylactic and curative agent against scabies and is an effective means of controlling the disease in an infected community.

We are greatly indebted to Prof. H. A. Krebs, Director of the Sorby Research Institute, who allowed the volunteers at the Institute to assist us in carrying out the investigation. We have also to thank Imperial Chemical (Pharmaceuticals) Ltd., who, in collaboration with Messrs. Lever Bros. and Unilever Ltd., supplied us with the impregnated soaps used in our experiments.

Medical Memoranda

Ischio-rectal Abscess Obstructing Delivery

The following case seems worthy of record because the condition must be rare:

A primipara aged 25 had been troubled with intermittent attacks of cystitis due to *B. coli* for the last three months of her pregnancy. The attacks were easily controlled by giving the patient 10 c.cm. of a 20% solution of calcium chloride in a glass of water twice daily. This treatment had been recommended to me by the late Sir E. Sharpey-Schafer, who found that this solution of calcium chloride rendered the urine acid (*p*H 5) and so inhibited the growth of B. coli.

With the onset of labour the patient complained of pain in the perineum at a point about " 7 o'clock " with reference to the anus. At this point there was a firm elastic swelling about the size of a golf ball. When the head came down on the perineum the patient was unable to exert any pressure to help delivery because the pain was so intense; and the swelling was making the perineum rigid and thus holding the head back. The swelling was an ischio-rectal abscess, and to avoid rupturing it I did an episiotomy on the left side of the vagina and delivered the head by forceps. Three days later the abscess was opened and drained after the vagina had been carefully shut off with sterile gauze. A sample of the pus yielded a pure growth of *B. coli* (R.C.P.Ed. Lab.).

Recovery was uneventful. A subsequent pregnancy in three years' time was perfectly normal, with no recurrence of the *B. coli* infection.

I am indebted to Prof. Learmonth, Department of Surgery, Edinburgh University, for his kindly interest in this case.

A Case of Uterus Didelphys

The following case should be of interest on account of its rarity:

HISTORY

An unmarried girl aged 26, serving in the W.A.A.F., was admitted to an E.M.S. hospital complaining of dysmenorrhoea. Appendicectomy had been performed six years previously for acute appendicitis. She had amenorrhoea for six months after the operation, and since that time had suffered from severe dysmenorrhoea; otherwise her menstrual history was normal. Puberty occurred at 16; periods were regular 3/24 with the above exception. Her symptoms of dysmenorrhoea had been very distressing, the pain being of greatest intensity six hours premenstrually and lessening to some extent once the flow started. She described no other abnormal symptoms of particular note.

On examination the patient was seen to be well developed physically and secondary sexual characteristics were well marked. No abnormal physical signs were demonstrated. Vaginal examination under pentothal-gas-oxygen anaesthesia revealed the following points: Two intact annular hymena were present, together with two distinct vaginal canals, of equal size. The mucous membrane appeared normal. There were two distinct cervices, small but nevertheless not rudimentary. Both cervical canals were patent. A uterine sound was passed into each canal for a distance of 2½ in. in the direction of retroflexion, and failure to " click " the tips of the two sounds indicated the presence of a double uterus. Bimanual examination then revealed a distinct sulcus between the two uteri and that both were retroflexed.

Lipiodol injection of both sides, carried out with direct visualization under pentothal-gas-oxygen anaesthesia, demonstrated conclusively the existence of two distinct uterine cavities and also that on each side the Fallopian tube was patent. The lipiodol, however, escaped rapidly into the pelvic cavity and the radiographs were not very satisfactory.

REMARKS

The above is an instance of one of the extreme types of duplication of the genital tract due to failure of fusion of the Müllerian ducts in their whole extent, the defect having arisen early in development before their differentiation. The uteri were fused only at their cervico-vaginal portions, and even then fusion was incomplete. It represents, in fact, a true uterus didelphys, of which there are very few cases on record. The most extreme case, described by Gemmell and Paterson in 1913, in which duplication of the vulva and also of the urinary tract was observed, shows the end-results of failure of fusion of structures other than the Müllerian ducts; but the case I have described presents features of Müllerian origin only, though in a very complete form. In cases of uterus didelphys the hymen is usually single, but in this instance there was definite duplication. Otherwise the case does not differ essentially from those already on record.

It will be of great interest to follow the progress of this case and, in particular, to learn of the details of the first pregnancy.

I am indebted to Mr. G. S. Davidson, consultant gynaecologist, and to Col. G. M. Millar, medical superintendent, for granting me permission to publish this case.

Reviews

MEAKINS'S PRACTICE OF MEDICINE

The Practice of Medicine. By Jonathan Campbell Meakins, M.D., LL.D. Fourth edition. (Pp. 1,444; illustrated. 50s.) London: Henry Kimpton. 1944.

Prof. J. C. Meakins rightly regards the practice of medicine as probably the most entrancing profession in the world, requiring as it does an understanding of and sympathy with all aspects of human life. The day of the family doctor is held by some to have passed away. This he thinks would be unfortunate, for the physician who knows the patient from birth has a perspective to which no one else can attain. Modern developments have improved technique and raised the average health of the community; but he asks, " Has it done so without the loss of a certain finesse and understanding of the human frailties and the helpful counsels of an old and trusted friend which made medicine a profession and not a trade?"

It is in this spirit the author conceived his textbook *The Practice of Medicine*, which has now reached its fourth edition. Naturally this new one is tinged by his war experiences as Brigadier and Deputy Director of Medical Services, R.C.A.M.C., leading to such topics as the crush syndrome, the hepato-renal syndrome, blast injuries, jaundice after administration of human serum, and the epidemic type. Each of these has as a matter of fact thrown important light on the pathology of the diseases of civil life. The sulphonamides and penicillin receive due consideration, as does malaria—now a world-wide problem in prophylaxis and treatment. Atypical or virus pneumonia has become a clinical entity. The study of traumatic shock, for which there has been such abundant opportunity, has clarified our concepts of disturbance of psychological balance, and thrown light on the sequence of events in burns and in dehydrating diarrhoea. All this has led to extensive revision in view of the new knowledge. Throughout we see the impact of military experience on civilian life.

Due emphasis is laid on the importance of diet and proper housing in the maintenance of health—and on the trend towards a preventive attitude. The other great factor in the forward march stressed by the author is the rapidly advancing concept and understanding of psychosomatic processes, for there is hardly a region of the body where this does not apply. Prof. Meakins has a decided belief in the value of visual impressions and has therefore enriched his pages with 517 illustrations, 48 in colour. It is an excellent if somewhat monumental tome of more than 1,400 pages. We may well ask, How much will examiners expect the student to remember?

OBSTETRICS AND GYNAECOLOGY

Combined Textbook of Obstetrics and Gynaecology for Students and Practitioners. Fourth edition. Revised by J. M. Munro Kerr, R. W. Johnstone, James Hendry, Dugald Baird, James Young, Donald McIntyre, E. Chalmers Fahy. With additional contributions by Charles McNeil and G. Jackson Wilson. (Pp. 1,208; illustrated. 42s., plus 1s. postage.) Edinburgh: E. and S. Livingstone. 1944.

This excellent combined textbook has been completely revised in its fourth edition and is now better than ever. It can be warmly recommended both to medical students and to general practitioners, and the price of 42s. is most reasonable. We would agree with the authors that a textbook of this type is not the place to discuss the finer points of surgical technique, nor is a volume written primarily for students the place to discuss the details of the more difficult problems of differential diagnosis and treatment in either obstetrics or gynaecology. Such topics have been skilfully handled throughout the book. The revised section dealing with analgesia and anaesthesia brings this subject up to date with references to cyclopropane anaesthesia, pudendal and parasacral blocks. The importance of the Rh factor in obstetrics receives due attention. Illustrations are for the most part excellent; but Fig. 224 depicts a type of episiotomy which it is doubtful whether any of the authors would perpetrate. One or two of the plates illustrating points of radiological interest are a little heavy. It is somewhat surprising to find pituitary extract in doses of 1 c.cm. being advised in the treatment of obstetric shock and in the control of post-partum haemorrhage, and one cannot help wondering whether the high mortality apparently associated with manual removal of the placenta in the experience of the authors might not have been due to the use of this drug under these circumstances. In discussing the treatment of the extended breech it is still advocated that a foot should be brought down early in the second stage, and many readers will feel that episiotomy is not given the place it deserves in the conduct of a breech delivery. Apart from these points of criticism the teaching throughout is conservative and orthodox. It is clearly expressed and well illustrated in a way which will appeal to students and doctors alike.

OPERATIVE SURGERY

Operations of General Surgery. By Thomas G. Orr, M.D. (Pp. 723; with 1,396 step-by-step illustrations on 150 figures. 60s.) Philadelphia and London: W. B. Saunders Company.

Textbooks of operative surgery fall roughly into two categories. The one, which may be called, perhaps not too aptly, academic, eaches the classical operations in detailed steps and is that most used in the teaching of the subject to students for examination purposes. The other type, of which *Operations of General Surgery*, by Thomas Orr, professor of surgery at he University of Kansas, is an example, gives a much scantier account of operative technique, but covers a very wide field and is less concerned with the classics. For this reason such books tend to be more absorbing to the student reader, who possibly gets the impression that he is exploring the exciting newer surgical fields without the irksome and tedious necessity for concentrating upon the "donkey-work" so essential to the acquiring of a sound surgical ability. To read these books s as delightful as listening to a good recording of Kreisler or Menuhin playing, without having one's attention unwillingly drawn to the painful scrapings of the violin aspirant as he applies himself over the weary hours to his practice exercises. Since the great majority of students will not practise surgery his method of approach may be quite proper; it is certainly more popular in the United States than here. For the budding surgeon, however, there is no short cut; he must rely upon the older fashion of book, of which luckily there are several excellent examples in our literature. Their rather heavy going can be relieved from time to time by reading a chapter or two of the former type.

In the volume under review the whole range of general urgery is covered in an attractive way; the many illustrations are of as high a quality as the text. We cannot help feeling, however, that in the matter of balance between the sections he author has not been entirely happy; there is a tendency o describe new and attractive procedures at length while omitting other matters of greater frequency and importance. As an example, adrenalectomy, thymectomy, and operative obliteration of the ductus arteriosus are described at length, but there is no account of the surgery of intracranial tumours or abscesses, of pituitary tumours, nor indeed is there anything o tell the surgeon how to enter the skull in these cases. Perhaps this lack of balance is best assessed by noting the space devoted to each section. Thus the whole of nervous surgery, ncluding the peripheral nerves, the spinal cord, and the brain, s dismissed in 24 pages, while the sympathetic system alone occupies 19 pages; in the thoracic section of 56 pages the losure of chronic empyema cavities takes no fewer than 2 pages.

The general standard of production of the book is very good, he semi-art paper used allowing excellent reproduction of the lustrations, but we think the author must revise the balance f the various sections in any future editions.

ENDOCRINOLOGY

Recent Advances in Endocrinology. By A. T. Cameron, D.Sc., F.R.I.C., F.R.S.C Fifth edition. (Pp. 415; illustrated. 18s.) London: J. and A. Churchill. 1945.

The fifth edition of this well-known textbook has been largely rewritten in order to pay more attention to the clinical aspects f endocrinology without increasing the size of the volume, hereby adding to its value to the practitioner. The principal ew points which the author stresses are the light that the use f radio-active iodine has thrown on thyroid function, the lose association between the parathyroids and the control of phosphate excretion, and the clearer knowledge of steroid hormone chemistry. He believes that the posterior pituitary produces only one hormone, and that Fröhlich's syndrome is not endocrine in origin, while renin produced by the kidney must be regarded as a hormone. Throughout insistence is laid on the use of accurately standardized preparations of known activity. This remains one of the best textbooks on endocrinology, and is all the better for retaining such a manageable compass.

Notes on Books

Malnutrition (Quaker Work in Austria, 1919–24, and Spain, 1936–9), by NORAH CURTIS and CYRIL GILBEY, is published at 2s. by the Oxford University Press, and it recounts the work done by missions sent out by the Society of Friends. The events in Austria and Spain left Europe hungry and with millions of children suffering from malnutrition, which is more intractable than famine. Famine happens to a whole community living in a definable area: therefore it is less difficult to know whom to feed. Malnutrition, however, with its lowered disease resistance, requires special supplementary diets for selected children in the birth-to-six-years range, so relief measures must be based on extensive individual inquiry and medical supervision. The vast experience of the Society of Friends has shown them the best methods of rehabilitation in undernourished families and disrupted homes. Quakers realize that the New World cannot be securely built save on the restored health of the peoples. This booklet tells how the Society deals with the problems. First it makes a survey, and this is followed by food relief, through welfare centres, distribution depots, and children's homes. The administrative centre works in co-operation with Governments and local authorities. Though in very condensed form much valuable information is given. The authors find that methods useful in one country are inapplicable in another and that malnutrition can be dealt with only by common-sense handling of each situation. The recent debate in Parliament, introduced by Earl Winterton, has proved the urgent need for more active consideration of post-war starvation.

Miss EVELYN C. PEARCE'S *Medical and Nursing Dictionary and Encyclopaedia* appeared originally in 1933 under a shorter title. It was written from great experience as sister-tutor for many years at the Middlesex Hospital and as an examiner of nurses. The author's intention was to give her readers a general view of the treatment and nursing of the disorders and diseases they would meet in their work, and assist them in preparing for the final State examination. In the course of revision at frequent intervals the contents have grown, and for the seventh edition (Faber and Faber; 12s. 6d.) a great deal of material has been rewritten and new information added. It is a very comprehensive book, and the fact that it extends now to well over 700 pages will hardly be realized at first glance. The slimming process has been accomplished by wartime methods of printing and production, but the type is clear and the paper reasonably opaque. As before, the nursing details are given in excellent fashion, and the book may be recommended with confidence.

A sixth edition of Dr. E. B. JAMIESON'S *Companion to Manuals of Practical Anatomy* has appeared three years after the fifth, and it well maintains the principal characters of the previous issues—namely, a concise statement of the essential elements of human anatomy dealt with in the main from the systemic standpoint; but where in the opinion of the author it has appeared advantageous to treat the subject from the regional standpoint he has not hesitated to include short general descriptions of the position and relations of the contents of such parts as the axilla or popliteal space, or the general anatomy of such regions as the suboccipital triangle, inlet of the thorax, perineum, palm, or sole of the foot. The 35 pages devoted to development require illustrations to render them easily understood by a beginner, and although without these the verbal description may serve more advanced students as a reminder of some of the principal stages in the formation of the embryo and its appendages, it is doubtful whether this short epitome of a large and important subject will be of much value, except for the purpose of revision. The *Companion* considered as a whole is a straightforward statement of the main facts of macroscopic anatomy, clearly expressed and remarkably free from errors. It is well produced in a convenient form, so that it can be carried in a pocket and studied at odd moments. The Oxford University Press publish it at 16s.

Dr. Lewis Smith, consulting physician to the London Hospital, who died at Criccieth on Sept. 17, left estate valued at £98,236. He bequeathed £20,000 to his wife, and, after other bequcsts, the residue on trust for her for life, and then £10,000 to the London Hospital Medical College, to provide a Lewis Smith scholarship in clinical medicine, and the remainder to the Royal Medical Benevolent Fund.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 10 1945

CLINICAL SCIENCE AND MEDICAL TEACHING

At the end of the last war there was little doubt in men's minds about the best method of clinical teaching. The student was enjoined to work hard at his pathology, and he was told that if in addition he attended regularly in the wards he would have little difficulty in learning the art of medicine. In Osler's textbook descriptive medicine reached a peak from which it has steadily declined as textbooks have become more compendious and less vital, and MacCallum presented pathology with equal charm as the science of the reaction to injury. The circumstances which have disrupted this happy state of affairs are not far to seek. The first was the development of ancillary methods of investigation, particularly biochemistry and radiology. The second was the increasing tendency to specialization and fragmentation of the clinical field. The third was the advance from the therapeutic nihilism of Osler's generation to the therapeutic successes and prospects of to-day. The result is that after this second world war a radical revision of the curriculum seems desirable, but we have not yet reached agreement on how it is to be achieved. A number of general principles have been enumerated, more particularly in the Goodenough report, but difficulties soon arise when one attempts to deduce from them the actual details of a course. These difficulties are especially great if it is agreed, with the Goodenough Committee, that the medical course must be kept at a reasonable length. The decline in the birth rate and the financial stringency to be expected after the war are strong reasons for trying to get medical students qualified and on the *Register* within a period of 5½ years.

The Goodenough Committee unfortunately did not discuss the motives which cause students to take up medicine as a career and the incentives which inspire them at various stages of their course; nor does its report attempt a "job-analysis" of the physician's work, particularly in general practice. Psychological factors must obviously be considered in relation to the gap between pre-clinical and clinical studies which the Goodenough report is so anxious to bridge. The pre-clinical student is a university student, living in the academic world, attempting to learn to live the good life, to have a disinterested love of knowledge, and to share in the social and athletic life of a homogeneous community. The clinical student becomes an active member of a heterogeneous community in the contemporary world, and his outlook on life changes. He comes under the influence of teachers whose business is the healing of the sick rather than the acquisition of knowledge. His attention turns from ideas to people, and in nine cases out of ten his most powerful motive is to qualify as rapidly as possible. His enthusiasm for the pre-clinical studies in which he had hitherto found so much satisfaction fades for a time, and classes in applied anatomy and physiology are commonly felt to be a sterile academic exercise. If the psychology of the student stands in the way of the integration of pre-clinical with clinical studies, the psychology of the teachers and the nature of the material to be taught stand in the way of the correlation of the clinical studies, in particular pathology and preliminary medicine. The study of reactions to injury has usually followed the route of general pathology first and special pathology later, which is not necessarily the best approach to the patient. While it is easy enough to arrange special pathology in parallel with clinical studies of the same types of disease, it will be harder to co-ordinate the important first steps in general pathology and clinical science, both with each other and also with the pre-clinical studies which have gone before.

Another popular generalization is that clinical medicine must be more scientific and that emphasis should be placed on the inculcation of fundamental principles and methods, rather than on purely factual knowledge. It is not clear what these fundamental principles and methods are. The pathologist may interpret them as the methods of the experimental laboratory, the clinician as the exact analysis of the mechanism of symptoms. The methods which led Astwood and his colleagues[1] to the discovery of thiouracil are surely quite different from the methods by which Sir Thomas Lewis's pupils have analysed the nature and meaning of the eye changes in exophthalmic goitre.[2] The value of the experimental method in research is indubitable. What is in question is its adoption as the basis of clinical teaching. In other words, are we to attempt to maintain an active and progressive interest in the biological and physical sciences while the student is learning clinical medicine, or are we to concentrate on teaching the interpretation of symptoms in physiological and psychological terms? The former course would certainly seem to invite producing neither a good scientist nor a good doctor, for experience suggests that no one could satisfactorily carry out two such exacting disciplines at the same time. During the years in hospital it will take the student all his time to learn the grammar of clinical science, the applications of statistics, and the appreciation of the psychological factors in illness.

These thoughts have been stimulated by the publication by Sir Thomas Lewis of a book on *Exercises in Human Physiology*.[3] This book is based on the belief that just as the student has class exercises in physics or biochemistry so he should have class exercises in clinical science. Sir Thomas disarms criticism by not attempting to cover the whole field. The exercises are in fact based on his own work and deal mainly with the study of the circulation, the reactions of the skin, and the investigation of pain. A book by Sir Thomas Lewis is always a major event, and this one is especially important because it gives form to the vague idea of the inculcation of methods and principles, and it projects a bridge between the pre-clinical and clinical studies. Such a course would almost certainly require the help of clinical teachers, and this would ensure that the bridge between physiology and medicine was open to traffic. Only practical experience can show whether such a course would arouse the interest of the student and whether the gap between these exercises and the examination of patients was narrow enough for the transfer of skill and principles. The difficulties in the physiological approach to medicine are twofold. Only a proportion of signs and symptoms can be analysed physiologically, and those are often the gravest ones. It may be a fascinating exercise to classify different varieties of leukaemia or to analyse the symptoms of terminal heart failure in hypertension, but the student often finds it unreal and lacking in humanity. The second reason is that many of the commonest symptoms, particularly in the gastro-intestinal tract, are better analysed in psychological than in physiological terms; the organ's specific function is being used to express a tendency of psychic direction.[4] Nevertheless in a synthesized course of teaching it will probably be wisest for the student to begin with the physiological analysis of isolated symptoms, to proceed to the examination of systems and the consideration of the effects of disturbance of the function of organs, and to arrive finally at the study of the patient as a complete and sentient being. Sir Thomas Lewis has given the lead in the devising of such a course, and it remains for others to develop and expand it.

HEALTH OF NEW YORK IN 1944

The review of the vital statistics of New York City by the Health Commissioner shows some interesting contrasts. The birth rate at 16.0 per 1,000 was 1.6 and 1.4 below the high levels of 1943 and 1942, but with these exceptions it was the highest rate since 1931. For the second consecutive year there was a rise in infant mortality, the rates for 1942–4 being 28.8, 30.2, and 31.2. Practically the whole of the increase occurred during the first month of life, and mainly between the ages of 10 days and 1 month, the causes responsible being diarrhoea and congenital malformations. The maternal mortality rate, at 1.8 per 1,000 live births, was the lowest ever recorded, and about one-third of the rate prevailing ten to fifteen years earlier. Another " all-time low " was provided by the small number of 242 cases of diphtheria during the year, with 7 deaths. The falling incidence of this disease may be justly attributed to widespread immunization. During 1910–19 the average number of cases was 14,282, with 1,290 deaths. From 1920 to 1929 the averages improved to 10,685 cases and 704 deaths. Notifications of whooping-cough at 2,809 cases and 34 deaths showed a fall of 25% from the low level of 1943 and reached the lowest figures yet recorded. It is not stated whether and on what scale whooping-cough vaccine was used prophylactically. Measles was slightly more prevalent than in the previous year, there being 21 deaths. At the beginning of the year the Health Department made available a certain amount of gamma globulin for infants and debilitated children exposed to measles. The incidence of scarlet fever was about 10% below that of 1943 but 20% higher than in the two previous years; 8 deaths were recorded. In common with many other areas of the U.S.A. there was a large outbreak of poliomyelitis in New York City, with 1,907 cases and 102 deaths. This was the largest number of deaths from poliomyelitis since 1931, when 504 patients died and 4,138 cases were notified. The other large recent outbreak was in 1935, with 2,054 cases and 91 deaths. The incidence of meningococcal meningitis, which rose to a high level in 1943, fell, but was still higher than in any other year since 1905. The numbers of cases for 1940–4 were 48, 118, 411, 1,406, 1,115. Deaths for 1944 numbered 195, giving a case fatality rate of 17%, compared with 50% a few years earlier before the introduction of chemotherapy. Notifications of typhoid fever remained at the same level as in 1942 and 1943, but the deaths rose from 5 to 14. The mortality from tuberculosis has never been so low before, the rates per 100,000 being 46.0 for all forms and 42.3 for pulmonary tuberculosis; but these figures do not represent the total mortality, as some 500 deaths of city residents occurred outside the boundaries of New York and are not included.

New low records were reached in the mortality from appendicitis, accidents, and suicide, with rates per 100,000 of 5.1, 45.7, and 9.2 respectively. The death rate from diabetes, which had risen from 25.7 in 1930 to 42.8 in 1943, fell to 40.8 per 100,000. The death rate from cancer—177.2—was the highest ever recorded. Improved diagnostic techniques and the ageing of the population are important factors in the rising trend of mortality from this disease, which has increased by over 50% during the past fifteen years; but there has probably been a real increase in cancer. Mortality from cardiovascular-renal diseases—495.1 per 100,000—was lower than in 1943, but otherwise it was the highest on record. The death rate of pneumonia at 45.2 was below that of 1943 but above the rates of 1941 and 1942. The cumulative effect of the varying mortality trends was to yield a total death rate of 10.3 per 1,000—0.6 below that of 1943, but with this exception the highest rate since 1937.

In the campaign against tuberculosis the Health Department introduced for the first time a tuberculin-testing of pupils in vocational high schools. The positive reactors —19% of the 11,950 tuberculin-tested students—were then examined by *x* rays, and 27 were found to have tuberculosis. All school-teachers and school employees are to be *x*-rayed. So far 3,000 persons in private schools have been examined, and arrangements have been completed to deal with the public and parochial schools. Since Pearl Harbour the increase in venereal disease has caused the authorities anxiety. The brunt of this falls on the 15-to-19-year-olds, in whom early infectious syphilis was 204% higher than in 1941 and 31% higher than in 1943. The incidence of early gonorrhoea has also steadily increased. A new treatment centre was opened during the year making twenty in all. These clinics dealt during 1944 wi
68,000 patients. Because of the extent of the prob
special efforts were made to obtain the co-operati
parents, teachers, and clergy in the various anti
campaigns. In view of the large outbreaks of pa
in England and Wales in the early years of th

of the present very high level of dysentery in this country, the lectures and demonstrations arranged by the Health Board in New York for the numerous wartime restaurant workers are interesting. These covered "personal hygiene," "proper methods of food handling," and "restaurant sanitation," and were attended by over 2,000 workers. The department condemned almost 2,000,000 lb. of food as unfit for human consumption; perhaps the food situation in America allows of a higher standard than was possible in this country. An epidemic of rabies broke out in the spring, and a total of 34 dogs and 1 cat were affected during the year. One human case, which was fatal, resulted from a dog-bite. Over 27,000 dog-bites were reported to the Health Department—an increase of 4,000 on the previous year.

These are just some of the points of interest from the annual record of health and disease of one of the most important cities in the world, and once again we can only admire the promptitude with which the Health Commissioner gives an account of his stewardship for the year that is past. One impression that comes from perusal of these records is that the Americans are very much more "health-conscious" than we are, and that the American public responds much more readily to the ideas of preventive medicine put before them by an alert public health service. Perhaps it is that the American layman looks up to his doctor as a scientific technician who may be expected to know his own job. The British doctor does not seem to have the same prestige with the British public.

TOXICOLOGY OF D.D.T.

The new insecticide D.D.T. (2, 2, *bis*(*p*-chlorphenyl)1, 1, 1-trichlorethane) promises to be valuable in many fields. A knowledge of its toxicity to vertebrates and the probable hazard to man is most important. A number of independent toxicological investigations have been made, and the results of some of them are in print. A curiously common omission is the absence of statements about the purity of the D.D.T. used; commercial grades may contain anything up to 30% of impurities.

All investigators agree that D.D.T. is unlikely to cause dermatitis. In solid form it is not irritating to the skin, and even in strong solutions it produced only mild erythema in rabbits and nothing in man.[1] Absorption of D.D.T. through the intact or abraded skin of animals is very slight when the drug is applied as a dust (either neat or at 10% dilution). In various bland solvents, however, it is gradually absorbed and may cause intoxication. Even so, the acute lethal dose is high: D.D.T. dissolved at 10% in corn oil and applied in continuous contact under a rubber "cuff" failed to elicit symptoms in rabbits even at a dose of 940 mg. D.D.T. per kg. Solutions of 30% D.D.T. in dimethyl or dibutyl phthalate, however, brought on acute symptoms, but not death, at doses of 2–3 g. per kg. Daily repeated inunctions of these strong solutions were harmless to dogs (90 days), but killed rats, rabbits, and guinea-pigs after 5 to 10 applications of 4 c.cm. per kg. Smaller quantities (down to 0.5 c.cm.) produced chronic symptoms and often death after about 30 doses. Other workers[2] found D.D.T. more toxic; they report death of rabbits after about 20 daily applications of 50 mg. of D.D.T. per kg., dissolved in olive oil.

With regard to poisoning by mouth, there is again a big difference between solid D.D.T. (dispersed in mucilage) and D.D.T. dissolved in vegetable oils. The dangerous doses are much higher with the solid drug, presumably because of its non-absorption. With D.D.T. dissolved in oil, median lethal doses of from 150 to 750 mg. per kg were found for small laboratory animals.[2] [3] Goldfish have been killed by even lower doses (63–200 mg. per kg.) in oil solution.[4] The lethal action is erratic, which makes the precise limits of toxicity difficult to define. Chronic intoxication follows the addition of about 0.1% D.D.T. to the diet of small mammals and birds and may lead to death in a month or so.[2] [3]

The symptoms of D.D.T. poisoning are hyperexcitability and tremors, followed by depression and finally death. If the toxicant is removed at the stage of tremors, recovery ensues. With chronic poisoning there is loss of appetite and consequent emaciation, with increased susceptibility to various infections (which were often the final cause of death in the experiments). Post-mortem examination of intoxicated animals[5] [6] revealed little effect on the nervous system, despite the nervous symptoms. Most degeneration occurred in the liver after chronic poisoning. These toxicological findings are valuable in determining toxic limits and in indicating the most dangerous vehicles of D.D.T But it must be remembered that the doses employed are very large compared with those likely to be encountered in practice. If it is agreed that the most dangerous form is an oil solution it is reassuring to calculate that a 70-kg man would have to drink 200 c.cm. of a saturated solution in kerosene or 2 litres of a 0.5% fly spray in order to swallow the equivalent of the most cautious of the estimated lethal doses for small mammals (in this calculation the toxicity of the solvents is ignored). In the form in which D.D.T. would be met with by most people (as a dry powder or a crystalline deposit) it is practically harmless unless eaten regularly in small quantities. Despite the large quantities that have been manufactured during the past two years and distributed to the Services, and the continuous work on the stuff in numerous laboratories. we know of no case of human intoxication.

"ASIATICOCIDE" IN TREATMENT OF LEPROSY

The substitution of injections of soluble products of the fatty acids of chaulmoogra and hydnocarpus oils fo the oral administration of the nauseating oils themselve marked an advance in the treatment of leprosy, in spite of its failure in advanced cases and its smaller efficacy in the infective lepromatous form of the disease. A sulphon amide preparation, promin, has recently been reported by Faget *et al.*[6] to have given promising results by intravenou use over a period of two years. The discovery of a more effective curative remedy in all stages of the disease wil greatly facilitate the reduction, and eventual eradication of this ancient and justly dreaded scourge.

We have received, through the courtesy of the French Embassy in London, a copy of a dispatch from Madagascar giving a preliminary account of the discovery o a new remedy which is reported to have given remarkable results in the treatment of advanced lepromatous case of leprosy. In 1937 Drs. Boiteau and Grimes extracted new glucoside from an umbelliferous plant growing i

Madagascar called *Hydrocotyle asiatica,* which in doses near a toxic level gave encouraging results in leprosy. In 1938 Bontemps, working in the leprosy laboratory at Antananarivo, discovered a new glucoside, which he called “asiaticocide,” which was much less toxic; but it was insoluble in water, slightly soluble in alcohol, and very soluble in pyridine. By further research Boiteau succeeded in obtaining a solution suitable for injection. Devanne and Razafimahery in their turn have ascertained the chemical nature of “asiaticocide,” and Boiteau and Grimes are of the opinion that it acts as a solvent of the waxy coating of the bacillus of leprosy, which then becomes very fragile and may easily be destroyed by the tissues or by an adjuvant drug. In this connexion it may be recalled that in 1923 Leonard Rogers[7] recorded a note on the defatting action of injections of chaulmoograte's and morrhuates on the bacilli of leprosy and tuberculosis, based on estimates of the lipase in the blood of patients before and after treatment. The results now reported from trials of the new glucoside include softening, breaking down of nodules, followed by cicatrization. Healing of whitlows and perforating ulcers and gradual improvement of anaesthesia and muscular atrophy are also said to occur. Still more remarkable is the claim that eye lesions are rapidly cured if treated before the posterior chamber is involved. It has not yet proved possible to prepare large quantities of the new remedy for extensive trials, and in view of the many disappointments of recent years full reports of trials already carried out and their confirmation by other workers must be awaited. The most hopeful features of the present account of the work is the success in breaking down leprosy nodules, and still more the clearing up of the hitherto intractable eye lesions.

SCOTTISH INFLUENCE ON CANADIAN MEDICINE

Dr. D. E. A. Cleveland of Vancouver contributes to the January number of the *Canadian Medical Association Journal* an interesting paper on Canadian medicine and its debt to Scotland. The first name he mentions is that of William Cullen (1712–90), pupil at Edinburgh of Alexander Monro *primus.* Cullen was instrumental in founding the Medical School of Glasgow, and during his long life held the chair of medicine both in Glasgow and in Edinburgh. Dr. Cleveland recalls that it was in Edinburgh that the modern conception of medical education first developed and flourished and a generation of great teachers grew up there, led by Cullen, who was one of the first to give clinical lectures in Great Britain. “The essence of the Edinburgh method was the teaching of students at the bedside in hospitals directly connected with the medical school. . . . The influence of Scottish medicine appeared on the Canadian scene as the eighteenth century was entering its second half. Many Scots came to Canada after the conquest to engage in medical practice, and soon many Canadians were going to Scotland for their medical training . . . the name of Edinburgh and Scotland became synonymous in the medical relationships of Canada. Not a few of the men who represented Scotland and Scottish medical training in Canada are prominent, not only in the medical history of Canada but in the record of public life in Canada.” The names of Adam Mabane, Andrew Fernando Holmes, and John Stephenson are identified above all others with the beginnings of medical education in Canada. As a result of the energetic action of Holmes and Stephenson the Montreal Medical Institute grew out of the Montreal General Hospital. In Montreal at that time there was the anomaly of a medical school which actively taught but could confer no degrees and a university which could confer degrees but had done no teaching. James McGill was a wealthy Montreal merchant and a native of Glasgow, where he had attended the university. McGill College (later McGill University), so named in recognition of his bequest, had its actual beginnings as a functioning organization in a medical school, with its first teaching faculty composed entirely of Edinburgh medical graduates. But the Edinburgh tradition did not find its sole repository in McGill, for Scottish medicine played a large and important part in the establishment of hospitals and medical schools in Quebec among Canadians of French origin and speech. Scottish nationality and teaching, predominantly of the Edinburgh flavour, entered richly into the medical endowment of other parts of Canada also. About a hundred years ago 6 of the 28 practitioners in Toronto and 13 of the 14 in Halifax had been trained in Edinburgh.

DOCTORS IN HOT PRINT

There is an idea in many lay minds that the doctor—or at least their doctor—is a man apart: a man leading a dedicated life and immune from the ordinary whims and passions of mankind. The compliment has some justification in fact. Good doctors, by the nature of their job, are working philanthropists and have to be more than tolerant of human weakness and vice and absurdity. But beneath that professional detachment and that kindly avoidance of individual censure there lurks a person with feelings and opinions of his own. The long day's work, the multiplicity of the claims upon time and thought, will keep them under, but they are not abolished. A small irritant may goad repressed emotions into violent activity. The history of medicine need not be combed out for examples beyond mentioning antiseptic surgery and anaesthesia in childbirth, and psycho-analysis and contraception in the last 30 or 40 years. Euthanasia was a private matter between the humane doctor and his tortured and doomed patient, but when it became a matter of open debate there was a temptation for doctors to become publicists. One function of a medical newspaper is to give a platform for the interchange of knowledge and opinion. Much of medical practice is concerned with unpleasant facts and with the problems of sexual behaviour, normal and abnormal. Doctors can't be squeamish. A medical editor might like to “keep his columns clean”; but there are many things—and one of them is artificial insemination—which must be discussed sooner or later. What we have to bear in mind—and risk the consequences—is that doctors are not only humane but human (“The maxim's tremendous but trite”). Scratch the professional surface and the man or woman may emerge in unexpected shape as a politician or a theologian. No unguarded phrase in letter or article will escape the watchful eye and eager pen of the enthusiast. The correspondence columns of this *Journal,* week by week, bear witness to that, and there are many other letters which do not appear in cold (or hot) print. We try to hold an even balance and to give every view a fair hearing: it is better to err on the side of free speech than to stifle discussion. But there are limits, not to editorial patience, which is theoretically inexhaustible, but to the patience of the general body of readers, and a time always comes when it is plain that a heated and inconclusive correspondence has run its full course and ought to be wound up bef the antagonists have torn each other to pieces and a quieter people are bored to death.

Reports of Societies

VETERINARY AND MEDICAL CONTROL OF MILK SUPPLY

A discussion on veterinary and medical control of the milk supply took place at a meeting of the Section of Comparative Medicine of the Royal Society of Medicine on Feb. 21. Dr. H. J. PARISH, president of the Section, was in the chair.

Limits of Supervision

Mr. H. T. MATTHEWS, superintendent inspector, Animal Health Division, Ministry of Agriculture, who said that his remarks were personal and not official, described the milk industry as undergoing a slow evolution. In spite of all difficulties, milk-producing farms were producing more milk than ever before and the public were consuming more. Over a ten-year period production was up by about one-third and liquid consumption by two-thirds. The idea that medicine or veterinary medicine, either or both, should control milk supply was reflected in legislation which was framed to prevent the sale of unsound milk, but owing to the fact that milk was an important food it had been customary to regard all stages in its preparation as falling within the medical province. This was carrying a reasonable principle to an absurdity. It was like asking the doctor to supervise the cornfield, the poultry farm, and the trawler. Many people would say that medical control of milk supply had failed to prove effective, but his point was that the word "control" was wrongly used. If veterinary surgeons had been placed in charge at the distributing end with authority to work all the way back to the farm it would have been more productive of all-round benefit, but it would still have been illogical. No scientist with his limited view-point could control from without.

Cattle diseases in terms of human risk had been virtually reduced to two—tuberculosis and brucella infection. Both these diseases were of such economic importance in agriculture that their control or elimination was called for quite apart from human health. Of the measures now in operation against bovine tuberculosis, routine herd examinations could not have a substantial effect on total incidence until conducted with greater regularity and frequency than present circumstances permitted. The more regular use of tuberculin was becoming established. Of the milk sold in England, that from attested and tuberculin-tested herds was approximately 8%, and the number of cattle in such herds was over 700,000 and was increasing. But he did not think that any great reduction in bovine tuberculosis was to be expected over a period of years. As for brucellosis, the recently introduced system of vaccination with the American strain of the organism was proving very popular, and it could not be long before there was a heavily vaccinated cow population. Nevertheless, the attack on both these diseases could not be pressed to its ultimate extent until the veterinary profession was recruited to greater strength. There was no good evidence that non-tuberculous mastitis in the cow contributed to human ill-health, while actinomycosis of the udder was a pathological curiosity, if it occurred at all. The new arrangement for the control of the milk supply which placed veterinary science at one end and medical at the other had much to recommend it, but there was need for an intermediate link, which was being provided by the milk-testing and advisory service of the Ministry of Agriculture now being built up.

Medical Control

Dr. W. A. LETHEM, senior medical officer, Ministry of Health, said that for centuries local authorities had paid much more attention to prevention of adulteration of milk by water than to safeguarding milk from the health point of view. When, last century, attention was turned to health, the regulations were framed with a view to the elimination of bad smells, which were thought to be a cause of disease; hence rules were laid down for the position and construction of cowshed drains and so forth—provisions still incorporated in the Milk and Dairies Regulations. There were 1,500 local authorities interested in milk, and many a rural district council was expected to control 600 or 700 farms, so that it was not surprising that an overworked inspector paid more attention to structural matters, which were easily seen and supervised, than to methods of milking and handling. After the last war the mistaken assumption was made that cleanliness meant safety. The introduction of T.T. and pasteurized milk was a step in the right direction, but unfortunately a third class, Grade "A" (later "Accredited"), was included, which consequently was thought to be safer than ordinary milk; the cows from which this milk came, while subject to periodical clinical inspection, were not tuberculin-tested, the milk was no safer than ordinary raw milk, and was found for some reason to have a higher percentage of diseased samples. Milk from tuberculin-tested cows was on the whole free from tubercle bacilli, though not necessarily from the organisms of undulant fever or mastitis. If bottled on the farm, thus avoiding the risk of human infection at a later stage, it was known as "certified," but such milk was expensive and little of it was sold.

The public still had the mistaken idea that sampling for adulteration, with an occasional prosecution, indicated that their interests were being properly protected. The phosphatase test was the only really efficient test of pasteurization. There was no rapid test for pathogenic organisms. Under a defence regulation the Ministry of Food had power to specify areas in which only pasteurized or heat-treated milk, T.T. milk, or accredited milk might be sold. The only really safe milk was pasteurized or heat-treated (apart from dried or tinned), but Parliament had shown reluctance to make pasteurization compulsory. Medical examination and certification of milk handlers were impracticable, though a medical officer of health could prohibit the handling of milk by any person whom he suspected to be suffering from notifiable infectious disease. Medical officers of health were hampered by lack of adequate legal powers. They could stop the selling of milk which was believed to be infected with any human notifiable infectious disease, but not (except to a school under their own control) with tuberculosis, undulant fever, and mastitis, and it was not an offence to sell such milk, even knowing it to be infected. In such cases the medical officer of health simply notified the Ministry of Agriculture, which proceeded to trace and remove the cows at fault. When it was remembered that it took at least a month to test a sample—and that several biological tests were often necessary—it would be realized why it often took several months before the cow was discovered, during which time the milk continued to be sold. When the sample was from a bulked supply, drawn perhaps from several counties and dozens of farms, the search became almost an impossibility. Dr. Lethem mentioned an instance where three human cases of undulant fever were traced to the same T.T. producer-retailer, who refused to have his milk even temporarily pasteurized, and on whose farm, in spite of every effort by the Ministry of Agriculture, contagious abortion was rife.

A Producer's View

Mr. CLYDE HIGGS said that the first step in efficient control was a great improvement in the standard of livestock. He confessed himself not very happy about tuberculin-testing. He knew of cases of animals which were reactors at one time and non-reactors at another. Until recently he had been one of the crusaders for clean, raw milk. He had used the argument that if Nature had intended milk to be pasteurized she would have arranged that it came pasteurized from the cow. But he had now changed his mind as a result of various complaints, and had installed a pasteurization plant. He had no wish to improve bad milk by pasteurization, but he did want to make his good milk better still.

Dr. RICHARDS, agricultural bacteriologist, Reading University, referred to the unenlightened outlook of a proportion of operatives engaged in milk production. The gospel was not being got over to them. They were not hygienically minded or aseptically minded. He also criticized the decrepitude and squalor of many farm buildings. Without good structural arrangements, good supplies of water and the like, it was impossible to maintain normal hygiene and good husbandry. A good deal of the energy which the authorities directed to the upgrading of herds should be given to the upgrading of operatives and working conditions.

Finally, on this aspect of the discussion, Mr. J. L. DAVIES of the Milk Marketing Board, declared that farmers in general would subscribe to the opinions expressed in that meeting. The old debates on pasteurization were over. The desire for the elimination of animal disease and the improvement of the efficiency of herds was common ground. The trouble was that so many people seemed anxious to bring in more control and restriction and to make more difficulties for the milk producer. The matter was one, not for controversy, but for quiet co-operation between the medical and veterinary professions and the farmers.

The Powers of an M.O.H.

Dr. C. Fraser Brockington (Warwickshire) considered that much more attention should be paid to the epidemiological side of the problem. The practitioner of epidemiological science in a community was, of course, the medical officer of health, but a good deal could be done to strengthen his hands. It seemed to him that the milk operative should be a much more skilled craftsman. There should be registration of operatives. Every person engaged in any milk processing should be registered annually and undergo an annual bacteriological examination. It was, of course, true that a person might be certified free from infection on Dec. 31 and get Sonne dysentery on Jan. 1, but an annual examination would avoid a good many of the epidemics of typhoid fever which were caused by carriers. Perhaps even more important was the education, by film and otherwise, of operatives in the technique of hygiene. There was no reason why farm operatives should not be trained to be just as clean in their habits as nurses. If raw milk was sold he wanted the medical officer of health to have power to go to the farm and inspect it, with the right then and there to order the milk to be pasteurized or to stop the supply.

Other speakers on the veterinary side included Mr. H. W. Steele-Bodger, who said that the only way to get clean milk of good quality produced in this country was by payment of bonus; Dr. W. R. Wooldridge, who said that the conditions for the production of safe milk would never be forthcoming unless the medical and the veterinary professions and the producers combined in an appeal to the Government to facilitate the necessary provisions for animal health, adequate water supply, electrical or other power on farms, and the various other services which were available to most of the community; Dr. J. T. Edwards, who commented on the shortage of local surveys; and Mr. Steward, who strongly urged a supplementary biological examination of milk, and declared that T.T. milk should also be abortus-free.

The President (Dr. Parish) asked whether it was too much to hope that after the war pasteurization would be made compulsory, and that in districts where pasteurizing plant was not at present available official intimation would be given to the public that milk must be boiled before its consumption was allowable.

Openers' Replies

Mr. H. T. Matthews said that real control was coming from within. It should not be imposed from without upon the industry. The trouble at present was an over-diffused control. A recent survey had shown that in four adjoining counties there were as many as 348 persons who, by statute, should interest themselves in the milk supply. The result was that those who had the power did not exercise it because of their other multitudinous duties. If there were medical officers who thought that there was opposition to pasteurization from the veterinary angle they could be reassured. Pasteurization for the purpose of making milk safe was a medical problem, not an agricultural one. But it was well to remember the cost of pasteurization, which was something like twopence a gallon, or over ten million pounds a year.

Dr. Lethem, also in reply, said that he did not know what new powers Dr. Brockington wanted. The medical officer had ample power to go on to the farm. It was the local authorities which had not sufficient power. They could follow back human cases when these occurred, but they had no power to follow back bad samples. He had been asked what powers the medical officer had to control milk intended for schools and for nursing mothers. No milk could be provided for schools unless the medical officer was satisfied that the milk was free from disease. The medical officer could, and in some cases did, prohibit the supply of milk to schools. There were schools to-day with no milk at all because the medical officer. rightly, had said that he was not satisfied. As for nursing mothers, there was nothing to compel them to drink a particular kind of milk, although if they went to maternity centres—and the same applied to antenatal centres—they would find the issue of milk to such centres controlled, and it was the medical officer of health's duty to decide whether or not to certify.

HEALTH OF FRENCH CHILDREN DURING AND AFTER THE OCCUPATION

A meeting of the Section of Disease in Children of the Royal Society of Medicine was held on Feb. 21, Dr. Helen Mackay presiding, at which statements were made on the condition of children in the recently occupied countries of Europe.

Dr. Robert Debré, professor of paediatrics in Paris, an honorary member of the Section, who was in France during the whole of the occupation, gave an account of the condition of French children. He described the calamitous results immediately following the breakdown of France in 1940 and the long-continued deprivation of food by reason of the requirements of the invader, the requisitioning of transport during the occupation, and the lack of sea-borne food owing to the Allied blockade.

The result upon the health of the children was reflected in various statistics. The weight of newborn babies at the Bordeaux maternity centre during 1941–2 showed a fall from the average, but in 1943, thanks to an improved diet for pregnant women, the birth weights returned to normal. He gave the following table for the birth weights taken at the St. Louis Maternity Centre, Paris, comparing a pre-war year with two war years :

Birth Weights

	No. of Births	Under 4 lb.	%	4–6 lb.	%	6–7 lb.	%	7–8 lb.	%	Over 8 lb.	%
1935 ..	2,289	85	3·8	553	24·4	914	40	557	24·4	180	7·8
1942 ..	1,878	91	4·8	540	29·4	750	40	401	21	96	5·1
1944 ..	1,984	76	3·8	564	28·6	820	39	420	21	104	5·5

One effect of the shortage of milk supply was an increase in the number of nursing mothers. In one Paris district 90% of the mothers nursed their babies, compared with 38% before the war. According to one survey the mother's milk had roughly the same food value as before except for a slight diminution in phosphorus. After six months, however, it was usual for these under-nourished mothers to be unable to continue feeding their babies. A noteworthy increase of haemorrhages of the newborn had been ascribed to insufficiency of prothrombin, due to lack of vitamin K.

Children's Rations

The rations established in 1941 for children up to 3 years of age were approximately adequate, or at least sufficient to prevent loss of weight, though the milk situation was difficult; what was known as whole milk was actually skimmed milk, leaving only 30% fat. Rations for children from 3 to 6 were also roughly equal to the minimum necessary, but the rations for children from 6 to 13 were well below the minimum, and a boy of 18, requiring 2,400 calories a day, was allowed only 1,600. Shortage of fats and animal protein was the most unfortunate feature of the children's rations, which in January of this year became even worse, the effect of war operations in the rural districts of France preventing the town populations from receiving country supplies. He added that until the "liberation" the food changes did not affect equally all parts of France, and rural areas like Normandy, Picardy, and Brittany were spared under-nourishment, so that when last year the Allied armies entered these regions the signs of lack of food were not apparent. Indeed, the distribution of synthetic vitamins to children, at least in the Paris district, had prevented the worst effects of vitamin deficiencies. Working in a large children's hospital in Paris he had not noticed any increase in rickets, and scurvy was as rare as it was before the war. In less favoured regions, however, such as Marseilles, the picture was different. There a systematic survey of children up to 3 years of age showed clinical signs of vitamin D shortage in 54%. Since the "liberation" the food situation, instead of improving, had grown worse. It was difficult to obtain supplies of meat, vegetables, fruit, and eggs, while milk for children over 1 year was no longer allowed.

A comparison of the weights of 23,000 children in the Seine district over a period of six months in 1941–2, compared with the pre-war average, showed that 65% during those six months had increased by from 2 to 3 lb., whereas before the war the increase was from 3 to 8 lb.; 22.8% had not put on any weight at all; and 12% had lost from 1 to 3 lb. in weight. The children of from 14 to 18 had mostly lost weight. The National Department of Statistics had published the results of school medical examinations of 23,444 children, and these showed a very general decrease in weight of from 2 to 14 lb., according to age, as compared with the average weights in 1938.

Among infants gastro-enteritis, caused by impure milk, had been more frequent than before the war, especially in Southern France and Marseilles. In older children and adults an increased amount of dyspepsia was found, due to too much roughage. The seasonal incidence of diphtheria and typhoid had sharply increased, and while there had been no influenza epidemic, there had been much bronchitis and pneumonia.

Tuberculosis Rates

The most serious problem, however, had been the increase in tuberculosis. There had been an increase in tuberculosis mortality of 11% in 1943 as compared with the average of the years 1935–8. In some counties the increase had been enormous—in Bouches-du-Rhône, which included Marseilles, 74%, and in the Var, which included Toulon, 69%. He showed the following table of the death rate from tuberculosis (all forms) per 100,000 inhabitants in two regions, comparing the figures for 1943 with those for a pre-war year:

Age	Paris Region		Eastern Region	
	1936	1943	1936	1943
4 and under ..	78·7	93·0	34·0	55·6
5–9	36·5	37·1	21·0	36·4
10 14	35·7	47·7	27·9	42·2
15–19	125·0	130·0	91·7	103·0
20–24	178·0	277·0	136·0	166·0

In conclusion Prof. Debré wished he could state that things were now better, but that was not so. The milk supply in the large towns in the Mediterranean districts had never been so bad. There was no improvement so far as meat and fats were concerned. Many fears were entertained as to what would happen when the prisoners-of-war and deportees, large numbers of whom were known to be tuberculous, returned, and also as to the future of the devastated districts. On the other hand, the birth rate was rising. In 1943 it was 159 per 10,000 inhabitants, compared with 145 in 1938.

At the same meeting a report of an interim character, not yet available for publication, was given on the condition of children in Belgium. Dr. A. CAWADIAS, as head of the Greek Red Cross, gave an account of the very serious position in Greece. He said that the last report he had received showed enormous increases in the incidence of tuberculosis and of nutritional deficiency diseases. Greece was receiving only 29% of the required calories.

Dr. HELEN MACKAY from the chair said she hoped that public opinion would be aroused to hasten the necessary measures of relief to these afflicted countries. She felt convinced that adults in Great Britain would willingly accept a cut in their rations if it would benefit the children of Europe.

The Council of the Incorporated Association of Hospital Administrators (12, Grosvenor Crescent, London, S.W.1) announces that, by special resolution of the members, the name of the association has now been changed to the Institute of Hospital Administrators. At the time of the fusion in 1942 of the two old-established organizations, the Hospital Officers Association and the Clerks and Stewards Association, with a view to the formation of a single professional institute, all were agreed—as first choice—on the name now adopted, the less suitable title being taken only because legal difficulties, now overcome, prevented the immediate adoption of the more appropriate name.

Gas Gangrene after Secondary Suture of Thigh Wound

SIR,—Mr. J. Hamilton Barclay's case of gas gangrene following secondary suture (Feb. 17, p. 218) interested me greatly. I agree that surgical progress is encouraged more by a record and analysis of our failures than of our successes, but I fear that the conclusions and impressions I draw from the case are not the same as his.

In the first place I cannot refrain from commenting on the primary treatment of the wound before it came under Mr. Barclay's care. It is indeed distressing that at a C.C.S. in the fifth year of the war a large shell wound of the muscles should be considered "not suitable for surgical treatment," and to require nothing more than local "sulphanilamide powder and vaselined gauze." That this was a recent wound, that it was contaminated with soil and was in a known gas-gangrene "danger zone" (the thigh) merely aggravate the case. In my opinion all the subsequent disasters can be traced directly to this initial failure to incise, explore, and excise the wound.

It is not surprising that the wound was dirty and greenish six days later when it came under Mr. Barclay's care. The subsequent chemotherapy improved the surface of the wound; but without doubt there was dead muscle deeper down, and the gas gangrene flared up when the wound was closed by suture. The subsequent response to treatment emphasizes this point. In spite of intensive chemotherapy and multiple incisions, the infection persisted until Aug. 25, when a large slough was removed; thereafter the patient improved rapidly. It is reasonable to suppose that his progress would have been more uneventful if the devitalized tissues had been excised before infection had become established.

Mr. Barclay draws the conclusion that this case "emphasizes the necessity for taking swabs not only from the surface but from the recesses of the wound" and gives his opinion that the organisms (of gas gangrene) had been lurking just beneath the surface. I agree that the organisms were beneath the surface, but they were not in healthy tissues; they were in dead or devitalized tissues, and it is these which constitute the real problem of wound treatment. No bacteriological investigation, in my opinion, can replace surgical exploration, and no war wound should be sutured unless at some stage, early or late, it has been explored and all devitalized and dead tissue removed. The one great lesson to be learned from this case is that there is no substitute for adequate surgical treatment of a war wound. Any attempt to *replace* surgery by chemotherapy and bacteriology must lead to disaster.

The recovery of the patient from a condition so desperate is indeed a tribute to Mr. Barclay's untiring efforts, and he should be congratulated.—I am, etc.,

Oxford. J. TRUETA.

Osteomyelitis after Bone-marrow Transfusion

SIR,—In their article on tibial bone-marrow transfusions (Feb. 17, p. 220) Drs. F. W. Gunz and R. F. A. Dean appear to assume that the occurrence of osteomyelitis must be due to the introduction of sepsis by the operator. I do not think this assumption is quite justified, and for the following reason.

Over the past two and a half years in the course of upwards of 130 marrow transfusions I have encountered osteomyelitis in five cases. But over the same period and out of about 100 cases similar in type I have also seen it five times in patients who had received parenteral fluid only by some other route (subcutaneous 1, intravenous 4), the difference between the two sets being that in the marrow cases the osteomyelitis occurred always at the site of the needle puncture, whereas in the others it was not confined to the tibia (mandible, humerus, femur, radius, tibia). This last case is of interest, for had Gimson's needle been employed it would have been unjustly blamed. The infant in question received three intravenous perfusions, but the gastro-enteritis was only completely checked when pus began to accumulate in the knee-joint, the baby then becoming constipated (a teaser for those who hold that gastro-enteritis may be caused by concealed focal sepsis). *Staph. aureus* was grown from the pus.

Is it not then likely that whereas the site of an osteomyelitis will be determined by the trauma of the medullary needle the fact of its occurrence at all is due to bacteria already in the blood stream looking for a suitable nidus? I have had the opportunity of discussing these events with an orthopaedic surgeon of wide experience, who tells me he has seen a number of cases of spontaneous osteomyelitis in infants recently and considers the disease to be on the increase. Putting these facts together I think it likely that staphylococcal septicaemia, either as cause or complication of infantile gastro-enteritis, is commoner than is generally recognized, the trouble being that *Staph. aureus* is such a vulgar creature that when found in culture he is apt to be called a contamination rather than recognized as a pathogen; and clearly many cases will not determine as osteomyelitis, pyo-arthrosis, etc., since babies are poor hands at making pus. There is one other point: if you are to have an osteomyelitis it seems better to have it in a bone already drilled for drainage. Three of my five cases recovered with only minor surgery.

I doubt whether wearing gloves does much to prevent sepsis. The (Gimson's) needle need not and should not be touched by the hand of the introducer at all. I think the danger lies in the later stages, when a faulty connexion may tempt unsterile fingers to fiddle with it.—I am, etc.,

The Grove Hospital, London, S.W.17 JOS. B. ELLISON.

Nutrition at Home and Abroad

SIR,—I have read the leading article on the above matter (Feb. 17, p. 227) and I must say I find nothing to criticize in the conclusion you quote as expressed by Dr. Magee and the *Times*.

In my own small town I have been keeping close watch on the condition of children of all ages. In 1941 I confess I was alarmed at the condition of the school-children, whose rate of growth and physical efficiency (as judged by performance tests) were significantly lower than the pre-war level, but we all know now that in 1940 and early 1941, owing to the submarine blockade, Great Britain was in a precarious condition as regards food, especially those foods containing first-class protein.[1] In late 1942 and early 1943 the rates of growth in weight and height regained pre-war levels, though strength and endurance lagged behind.[2] Later these also regained reasonable levels.

Regarding younger children, an investigation was made by Dr. Lewis Faning and myself[3] of the rate of growth of children under 1 year between July, 1940, and July, 1942; note the former date especially, for it denotes that part of the time covered by this investigation was one of the worst in the war for food sufficiency, yet in this period, owing, I believe, to definite steps taken by the Government to provide milk and vitamins for expectant mothers and infants, these babies did not fare as badly, for we found as follows. The average weight and length and the rate of growth in respect of both those indices were compared as regards children attending clinics in Glossop in the two periods 1933–6 and 1940–2. There was sharp differentiation between the findings for the two sexes. Males in the second or war period, in the early weeks of life, on the average weighed less and measured less than those in the first or pre-war period. But the average rate of growth for the 1940–2 series was the faster, particularly as regards weight, so that not only were they heavier and longer than the pre-war group at the end of the first year of life, but the average of all weighings over the whole year of life was significantly higher by 0.17 ± 0.07 lb. Females, on the other hand, showed no difference between the two series as regards average rate of growth or in weight. But in average length there was a significant difference of 0.35 ± 0.07 in. in favour of the 1940–2 series.

Recently I have just been making comparisons between the heights and weights of school-children in 1934 in the piping times of peace and in 1944 during the stress of war (when the Government arranged a fair distribution of all available food). I find as follows. In weight girls of 11 years were up to pre-war standard while girls of 12 and 13 years were significantly better than the pre-war standard. Boys of 10 and 11 (taken together) were above the pre-war standard, boys of 12 years, 13 years, and 14 years were also all significantly better than the pre-war standard. The average mean weight of the boys of 12 was 4 lb. more than their pre-war brethren, the boys of 13 almost 5 lb. more, and the boys of 14 about 8 lb. heavier!

The data given (and not of a clinical nature) so far as it goes would seem to verify the assessments of surveys made and mentioned in the *Journal*. I have never been very much in favour of clinical assessment alone for the nutritional state, but I have reason to believe that with experienced workers it can be valuable, though confirmation by more objective measures is desirable. If the *Journal* cared to give me space I could enlarge on this matter and also, I think, make some very definite suggestions based on some experiment for the improvement of any adverse nutritional condition of children which the leader writer seems to imply is now existent in Britain.—I am, etc.,

Glossop. E. H. M. MILLIGAN, M.D., D.P.H.

SIR,—In your leader on this subject (Feb. 17, p. 227) you state: "The question of the relief of Europe is critical." Yes; because (to quote Charlotte Brontë) "misery generates hate," and we British, who have more food, fuel, and clothes, will be blamed if we do not insist that a fair share of these shall be distributed to the "liberated areas."

The military authorities have not organized any nutritional teams, and psychologically it is very difficult for them to turn their minds to such projects. U.N.R.R.A. has not been allowed to function in Greece, Belgium, or France, and cannot function unless it is invited to do so. The supply of food, railway engines, and motor lorries to France, for instance, is a question of priorities. No one wants to prolong the war, but since no one can promise that it will be won in time to gather this year's harvest in Western Europe, we must not lose the peace in our fear of prolonging the war.

On doctors, who know how necessary food is, rests a special responsibility to use whatever political influence they have for the sake of a decent Europe and for the sake of our colleagues abroad, who bear a much heavier load of frustration than we while they watch their patients die of undernourishment.—I am, etc.,

West Kirby, Cheshire. CHARLES BRUNTON.

Haemolytic Disease with Incomplete Rhesus Antibody

SIR,—The discovery by Race in this country and Wiener in America of an "incomplete" or "blocking" Rh antibody was the subject of a recent note in your columns by Race and Taylor (Dec. 9, 1944, p. 756), who described Wiener's technique for detecting the antibody. It may be of interest to draw attention to a case of haemolytic disease originally observed 18 months ago and recently reinvestigated by this technique.

The affected child was the second pregnancy, the first child having been normal. The blood groups were: mother, B, Rh-negative, St-positive, MN; child, A, Rh-positive, St-positive, MN (MN groups were kindly determined by Dr. G. L. Taylor). The mother's serum was examined on several occasions after delivery and no satisfactory evidence of an Rh antibody was found. Using 26 group "O" bloods very doubtful reactions were observed with 2 only (both Rh-positive). Dr. G. L. Taylor, who also examined the serum at this time for Rh antibody, obtained similar results and doubted the specificity of the reactions.

As serological evidence of Rh iso-immunization was lacking it was thought possible that the responsible haemolytic antibody might be maternal anti-A augmented through iso-immunization by the foetal A antigen. When the mother's serum was titrated anti-A was found in great strength (titre, 10,000 for A_1 cells), and it was concluded that iso-immunization by foetal A antigen had occurred. Confirmation of this iso-immunization has now been obtained by examining a recent specimen of the mother's serum and finding that the anti-A titre is now only 1 in 128. Wiener, however, has suggested that when the antigens A or B are abundantly present in the foetal body fluids (these children are salivary "secretors") the foetus is protected from haemolytic disease due to the corresponding antibodies, since these are absorbed by the plentiful foetal antigen without damage to the erythrocytes. The child's saliva was therefore examined and A antigen found in strength; the antigen was also readily demonstrable in the child's serum.

---

[1] *Food Consumption Levels*, H.M. Stationery Office, 1944.
[2] Annual Report S.M.O., Glossop, 1943.
[3] *Med. Off.*, Jan. 8, 15, and 22 1944.

The position then was this. Iso-immunization by foetal A antigen had occurred, but since the child was a secretor it was, on Wiener's hypothesis, immune to haemolytic disease from anti-A; Rh iso-immunization, though possible, lacked confirmation.

I have now re-examined the original serum by Wiener's technique, and the presence in it of an incomplete Rh antibody capable of inhibiting the agglutination of Rh-positive cells (Rh_2Rh_2 or Rh_2rh) by a standard Rh serum has been demonstrated; the incomplete antibody is still demonstrable in the recently obtained sample of the mother's serum. From this it is clear that Rh iso-immunization did in fact occur, and it seems probable that Rh antibody was responsible for the haemolytic disease. It is at any rate unnecessary to suppose that haemolytic disease due to anti-A occurred in a secretor contrary to Wiener's hypothesis.—I am, etc.,

Climate and Mortality from Burns

SIR,—The article on "Some Social Aspects of Burns in Glasgow" by Drs. Brown, Lewis-Faning, and Whittet (Feb. 3, p. 144) brings out a remarkable point—viz., that the mortality from burns is lower in England and Wales than it is in Scotland. Can this difference in mortality be due to the higher temperature of the air in the southern countries, perhaps minimizing shock, which is the chief cause of death? It may be of interest to record that in Singapore, where the air temperature ranges between 72°F. and 92°F. the whole year, fatalities from scalds and burns occur seldom, even when the lesions are extensive, and deaths are noticeably much rarer there than in Britain.—I am, etc.,

London, S.W.1.
KENNETH BLACK,
Ex-Professor of Surgery, Singapore.

The Prophylaxis of Trench Foot

SIR,—In your issue of Feb. 24 (p. 270) there appeared an article on this subject by Dr. Raymond Greene. In his second paragraph he makes clear that his article is "a summary of the teaching which has been given to a large number of medical officers of the three Services in the war medicine courses at the British Postgraduate Medical School of the University of London." As a regimental M.O. on active service on the Western Front during the war of 1914–18 I experienced the difficulties associated with this problem; and, in view of the somewhat novel nature of some of the teaching in Dr. Greene's article and its apparent impracticability under active service conditions, one naturally wonders to what extent the three Services and the British Postgraduate Medical School are associated with, and responsible for, the views expressed.

For instance, what evidence (if any) is there for this introductory statement: "It is the army in retreat, low in morale and with its communications in disorder, that suffers most severely"? And how is that statement to be correlated with the recent incidence of "trench foot" among our troops serving on the Western Front?

After stating that "it is the duty of the medical officer to see to it that his brother officers understand the reasons for the rules, and are continuously alert for breaches of them," the author proceeds to make the following surprising statement: "The man who breaks the rules and gets away with it is not a hero but a lucky fool. Moreover, he is a stumbling-block to those who are less well adapted, and he should be treated as a criminal." These are indeed strong words, and one must assume that the writer has given serious consideration to their meaning and implication before they were penned. Are we to assume that this statement has been made with the approval of the three fighting Services and the British Postgraduate Medical School?

But what are these "rules" which may mean so much to sailors, soldiers, and airmen? Here are a few of them, culled from Dr. Greene's article:

"The clothing must be as nearly as possible waterproof. . . . It should also be windproof. . . . The boots must be loose, supple, well oiled, and preferably without toe-caps. . . . Socks should be undarned, and also loose. . . . Garters and sock suspenders should be forbidden, the socks being kept up by pinning them to the pants." Inasmuch as the soldier does not choose his own clothing, one concludes that the responsibility for breach of this "rule" rests with the War Office and not with the men who have to wear the clothing with which they are issued. The serving soldier, before becoming liable to be "treated as a criminal" or dubbed as a "lucky fool," is surely entitled to know whether representations have been made by the University of London, the British Postgraduate Medical School, or Dr. Greene that all Army clothing *must* be supplied in accordance with the above specification; and whether the Army authorities have declined to take the action recommended. From my experience of life at the Front there should not be much difficulty in forbidding garters and sock suspenders; but I can think of no valid reason why the veto should not be extended to include rings on the fingers and bells on the toes. With regard to the suggested pinning of socks to the pants, we must again assume that the august bodies responsible for this "rule" have given to it the detailed consideration it merits.

"It is absolutely necessary that wet clothes, especially boots, socks, and gloves, should be changed at every opportunity. Combatant officers are sometimes inclined to regard such an instruction as 'soft'; they must be overruled." Overruled by whom? One must assume "by non-combatant officers"; and it would be interesting to learn what advice Dr. Greene would give to a non-combatant officer about to overrule a combatant officer during operations on active service. (For instance, during recent operations on the Western Front when our soldiers, according to official admission, have been wading about waist-deep in water.)

"A good method of drying boots is to lay a 6-foot length of gas-pipe across a brazier, push one end into the toe of the boot, and blow air from the other end with a bellows. If the business end of the pipe is made like a toasting-fork many pairs can be dried at once." No doubt; but there are a few minor points in this operation which require some elucidation. For instance, at what stage in the proceedings is it considered that the brazier should be lit, if at all? Of course the blowing of "hot air" should not offer any great difficulty to the old soldier. I am rather afraid, however, that he might experience some difficulty in deciding which is the "business" end of the gas-pipe—the one which is made like (and no doubt would be used as) a toasting-fork. At this point I should like to submit for consideration a suggestion which might be given a trial. If the other end of the gas-pipe (which, for purposes of differentiation, might be called the "pleasure" end) were suitably hammered out and curved it might be found of great value in picking stones out of horses' hooves; for I assume that one of the few regiments which could put the above operation into practice would be mounted—e.g., the "Gas, Coal, and Light Dragoons (the Gasoliers)." In the case of infantry regiments I have the impression that the "Lower Sixth Foot (Heath Robinson's Own)" might find some more useful adaptation for the "pleasure" end. However, these are more or less domestic details which we must leave to the discretion of the officers commanding the units concerned.

"The men must be taught not to stand still, slumped into their boots. . . . They must lie down whenever possible, with their feet higher than their heads. . . . They must not sit on seats, boxes, or firesteps in such a way that the popliteal space is constricted. They must on no account bring their feet near to a fire if they are cold or numb, but warm them between a companion's hands or inside his clothes."

So what?—I am, etc.,

Leytonstone, E.11.
A. W. FORREST.

Erythrocyte Sedimentation Rate in Infective Hepatitis and in Malaria

SIR,—In the *Journal* of Jan. 6 (p. 9) there is an article by Lieut.-Col. Paul Wood on the erythrocyte sedimentation rate in infective hepatitis and in malaria. He found the E.S.R. below 10 mm. in one hour in 85% of cases of infective hepatitis during the first ten days, and above 10 mm. in about 85% of cases of malaria during the first ten days, all by Wintrobe's method.

In tropical regions there is great difficulty in differentiating between sandfly fever and malaria in the very early stages. Sometimes malaria parasites cannot be found during the first four or five days of a primary attack of malaria, and confusion with sandfly is very common. I intended to write a paper on this problem of early diagnosis, and to that end made some hundreds of estimations of the E.S.R. (also using a modified Wintrobe method) on cases later proved to be of either malaria or sandfly fever. I agree with Col. Wood on the elevation of the E.S.R. in malaria; even in the very early stages I found the average case of malaria was about 20 mm. In sandfly fever, however, I found the E.S.R. very rarely higher than 10 mm.; the figures for both malaria and sandfly are one hour's observation of the E.S.R. Confusion between sandfly fever and infective hepatitis is unlikely as jaundice in sandfly fever is almost unknown. I cannot produce the figures on which my opinion is based, but I have been using the method for some years and have grown to rely upon it. Infective hepatitis is not unknown in tropical regions, so the method may prove of use to the Services there.—I am, etc.,

FRANK MARSH.

Persia. Pathologist, Anglo-Iranian Oil Company

The Psychiatrist and the Psychologist

SIR,—The annotation in your issue of Feb. 17 (p. 229) points out the big strides which have been made in the field of psychiatry during the war, and shows the important dependence of psychiatry and psychology on each other. There are some points, however, which would be the better for amplification. Your article points out that the training of the psychiatrist and that of the psychologist have proceeded along very different lines. This is true to an extent in that the psychologist has had no medical or psychiatric training at all, whereas the psychiatrist, especially if he holds a diploma in psychological medicine, has passed examinations in psychology. The training for such a diploma has included experimental psychology, which is the main subject used by the psychologist in connexion with vocational guidance.

Your statement adds: "The psychologist may have suggestions to offer on the subject of treatment." Unfortunately many psychologists, who have no right to do so, give much more than suggestions; they, in fact, take charge of the treatment and make no attempt to place the patient in contact with a medically trained psychiatrist. The patient often gains the impression that the lay psychologist is not only a doctor of medicine but also a specialist in psychiatry, whereas he has had no training in either of these fields. The result is that many cases in the end reach the hands of the psychiatrist, and much illness which could have been avoided has been allowed to develop. Thus many patients have become much worse than might have been the case had they been placed earlier under proper treatment. Your article rightly states: "In recent years, particularly in the field of child psychiatry, psychologists have sometimes embarked on a treatment of individual patients without adequate medical supervision. It is to be hoped that the unsuitability of this arrangement will be recognized by psychologists themselves." No doubt it is recognized by them, but they do not make any attempt to handle the situation correctly. Moreover, some local authorities are content to support child guidance clinics in which psychiatric advice is not given. The only medical opinion available in some of these clinics is that of the school medical officer, who often has had no psychiatric training or experience. The lay psychologist is placed in charge of the treatment of children when this is not the proper work of a psychologist.

In the latest report of the Child Guidance Council a list is given of seventy-five clinics recognized by the council. Some of these clinics also hold sessions at more than one centre. But of the seventy-five, only fifteen are listed as Group 1 clinics—that is, clinics which comprise a complete team of qualified staff: psychiatrist, psychologist, and psychiatric social worker. In many of the other clinics the treatment is not under the direction of a psychiatrist, and yet a number of them are being subsidized by local authorities. Apparently no attempt has been made so far to prevent an increase of this arrangement by further local authorities. Surely the Ministry of Health should be advised that in future it must not supplement grants made by local authorities to clinics at which the treatment is not directed by a psychiatrist—that is, by a medically qualified specialist in psychological medicine, who has been thoroughly trained in all branches of psychiatry, including neurology and psychology, but who may not necessarily continue to be a member of the medical staff of a mental hospital.—I am, etc.,

London, W.1. RALPH A. NOBLE.

SIR,—May I plead for a little of your space to comment on the annotation on the psychiatrist and the psychologist (Feb. 17, p. 229), the general tone of which, while stating that British psychiatry has made "big strides," rather fails to justify the assertion.

It is in fact as hard to know just where to join issue with the annotation as to decide what point it intended to make. Perhaps the greatest violence to the facts is done in the sentence which runs: "Where the psychiatrist approaches the problem from the point of view of the morbid the psychologist approaches it from the point of view of normal variation." Such a statement is not only derisory but is a criticism of psychiatry, revealing a deplorable lack of familiarity with modern psychiatric approach and, specifically, with the work of Adolf Meyer, emeritus professor of psychiatry at Johns Hopkins, under whom many British psychiatrists have studied during certainly the past thirty years.

If meiosis be allowable, it is disquieting to find in such an authoritative periodical as the *British Medical Journal* the implication that Meyer's concept of human personality, first formulated nearly half a century ago, is unknown in this country. This can hardly be true; at any rate one hopes it is not true of British psychiatrists, but one would wish the general body of the profession to be spared exposure to false doctrine. One cannot expect space for a formulation of Meyer's psychobiology, but one would ask to be allowed to point out that Adolf Meyer's concept of man's nature and his views as to psychiatric training (with which, be it repeated, a very large number of British psychiatrists are thoroughly familiar) have formed an accepted element in the training at the Johns Hopkins Medical School since about 1911 and in similar medical schools since that date. Its integral and basic principle is that the student must inevitably be trained first of all in the recognition of what comes within the elastic limits of the normal, and must know how wide these limits are before he can be allowed to approach the problems of abnormal behaviour.

If the annotation be a fair sample of the reactions to war psychiatry then indeed one feels, as Prof. Meyer recently said, "the war exploitations become overrated" (personal communication). The annotation alleges that the psychiatrist "is working by a rule-of-thumb method"—one would like details—when he says that an individual is unsuited to become an officer, and that this diagnosis may be shown to be wrong by the individual actually proving satisfactory; it asks, however, for the admission of "the greater appropriateness of the psychological techniques of . . . personal [sic] selection," when, in fact, it is widely known that "psychological techniques of selection" are repeatedly falsified by the performance of the subject under non-experimental conditions. *Naturam expelles furca tamen usque recurret.* One's experience with psychiatrists and psychologists alike is that as their experience with tests increases their faith declines.

It is really regrettable to observe in the annotation the spirit of mind-body dualism. Until this antique concept is finally put away, until psychiatrists are as familiar, and known to be as familiar, with the so-called normal as with the so-called abnormal, and until all who have to assume responsibility for living human beings are medically trained, any "big strides" may well be taken in the wrong direction. One's admiration for the regaining of equilibrium in the last few lines of the annotation is tempered by a feeling that the balance was lost unnecessarily.—I am, etc.,

Edinburgh. W. M. C. HARROWES.

Nursing and Tuberculosis

SIR,—Letters recently published on the incidence of tuberculosis among nurses suggest that doctors are concerned at the incidence of infection, but that few realize the enormousness of the problems which complicate the picture. Patching up the threadbare places will not do: a new garment is required.

A sanatorium is not the place of choice for the work or training of any girl under the age of 20 at least. The conditions of work in many sanatoria are deplorable. Old-fashioned buildings, lack of a good diet with an especial shortage of vitamins, antiquated schemes of nursing technique, and the dual role of being both "a pair of hands" and a student-nurse at the same time, all play their part in making the work hazardous for any young girl. Elementary precautions—such as the wearing of protective masks for intimate nursing procedures and the recommendations of the Medical Research Council to limit cross-infection—are regarded as measures too revolutionary to be adopted.

To remedy the situation nurse-training as a whole must be reviewed. The Horder report recommends that the student-status of the nurse in training should be fully recognized; that, by means of Government grant to the schools of nursing and by assistance where necessary for the individual student, student-nurses should cease to be the employees of their hospitals and pay (as other students do) for their training. In this way alone can nurse-training be truly established. At present student-nurses are a form of cheap labour, many of the lesser-grade training schools relying upon a minimum of student-nurses to get the ward work (including the cleaning) done. Dr. T. E. Bostock, in his letter published on Feb. 10, is quite right. Incredible though it may seem, many student-nurses in hospitals all over the country are sent into the wards upon arrival in an entirely "raw" state—whether Mantoux-tested or not. Practice precedes teaching in the majority of hospitals, the nurses learning by trial-and-error. Tuberculosis contracted during training may be the direct result of insufficient precautionary teaching either in the ward or in the class-room, or as a result of poor environmental circumstances.

The student-nurse of to-day is expected to learn a great deal, but she must learn always under difficulties, since teaching comes last in the consideration of many hospitals. When the student-nurse is also a poorly educated girl (coming forward in response to an appeal) and can scarcely write English, the strain experienced in learning anatomy, physiology, and hygiene is profound. But the student-nurse is there not only to learn: she must also get the work done, and so she must study, for the greater part, in her off-duty time.

It is a moot point whether the sanatoria produce more cases of tuberculosis among their nursing staffs than the general hospitals. The practice of training young nurses in the sanatoria before they do their general training should cease. All conditions likely to produce tuberculosis should be removed from the nurse-training schools. Such conditions are worry (e.g., about examination subjects), overwork, exposure to cold, poor nutrition, and exposure of the Mantoux-negative to massive infection. The Mantoux test should be made *before* any nurse enters a training school (too often this test is made *after* a girl has already been in heavy contact with the disease). Negative reactors should not nurse the tuberculous, and should be watched most carefully throughout their training.

Few of the improvements most urgently required in nurse-training can be brought about by the nurses alone: consent to improved nursing measures, for instance, must in many cases be obtained from the medical staff. Full discussion between *working* members of the two professions is most urgently needed.—I am, etc.,

J. EYRE.

Aural Barotrauma

SIR,—The late Sir Humphry Rolleston once said in a lecture to his students at St. George's Hospital (*Clin. J.*, Aug. 29, 1900) as follows: "First of all with regard to the word 'ascites.' It is derived from the Greek word ἀσκός, meaning a wine-skin; ascites, or in its full term, ἡ ἀσκιτης νόσος, is literally the wine-skin disease—i.e., that in which the abdomen resembles a skin distended with wine. The adjective 'ites' [ιτης] also seen in tympanites is much the same as the termination -itis (ῖτις)—e.g., in iritis and peritonitis—and is a feminine adjectival termination agreeing with the word νόσος (disease) understood. It is interesting to note that the termination -itis, which now always implies 'inflammation of,' has only acquired this meaning secondarily because the disease *par excellence* of various organs is inflammatory."

It would be possible, therefore, to defend the term "otitic barotrauma," to which Dr. A. B. Alexander objects (Feb. 24, p. 276), on the ground that barotrauma is substituted for the suppressed word νόσος, but as otitic implies inflammatory by common usage, which is the important point, either otic or aural would be better. I suggest that aural is preferable, though it produces a mixture of Latin and Greek, but the expression aural syringe is used without compunction. On the other hand, Messrs. Allen and Hanburys would certainly be astonished and perhaps puzzled by the receipt of an order from a purist in the Ministry of Supply for a few thousand otic syringes. Editorial permission is therefore requested to thank Dr. Alexander and to adopt the term "aural barotrauma."—I am, etc.,

YOUR ANNOTATOR.

Artificial Insemination

SIR,—It would be impossible to answer all the letters on this subject, even if we were to confine our attention to those which followed the publication of our article. Moreover, as many of these letters contain nothing but abuse, it would be unprofitable to answer them. We can assure those who invite us "to look this business fully in the face" that this was precisely what we hoped would be done by everybody when we submitted our report. It was an invitation to the medical profession to express an opinion on what was admittedly a highly controversial subject.

It must be admitted that the results have been very disappointing. The scientific aspects of insemination have aroused no interest, and the whole subject has been summarily dismissed as immoral by many. It should be noted, however, that the most hostile critics have been those who, having no first-hand experience of this subject, have been able to give free rein to their imaginations. We can assure these writers that adoption even if there were enough children to go round, does no always provide an adequate solution to the problem of the childless marriage. Nor does insemination with donated semen in our experience have a disruptive action on the marriage We have, indeed, known many cases in which the birth of a child through insemination has proved to be the turning-poin in a marriage which would have undoubtedly come to grie but for this happy event. It is only those who have had no experience of insemination with donated semen who would condemn it outright as a solution for certain chosen cases. I is, of course, mischievous nonsense to suggest that, if donated semen is to be used, it might just as well be administered in the natural way. The taking of a lover introduces a new relationship which in the end may prove disastrous to the marriage.

Nothing is easier than to render the idea of insemination with donated semen ridiculous or abhorrent by means o exaggeration. To reduce everything to an absurdity by thi means is a well-known polemical device, and it is not surprising therefore, that the opponents of insemination have visualized human stud-farms, professional donors, and a number of othe absurdities. That insemination has its ethical aspects we ar the last to deny, but we are still unable to see on wha grounds some critics dismiss it immediately as unchristianlike Christian morality is based on the Gospels and on the teachin of the Early Church, and when this morality was formulated the possibility of artificial insemination was not even considered Disputation would therefore have to be based upon th interpretation of other interdictions, and the condemnation o insemination with donated semen is certainly not so immediatel manifest that the subject need not even be considered. Sinc some opponents of this method of treatment are much concerned with the sin of masturbation we hasten to assure them that this particular difficulty can be overcome. This being so they may be prepared to consider the end in view—the birt of a child—instead of being entirely preoccupied with the means Unfortunately, in this correspondence the moralists have bee so preoccupied with the means that they have generall forgotten this end. Finally, we would call attention to the fac that we are research workers who happen to be interested i this particular field of medicine. We have invited the opinio f our colleagues on a very important subject, and not attempted enforce our personal opinions upon them.—We are, etc.,

London, W.1. MARY BARTON.
KENNETH WALKER.
B. P. WIESNER.

SIR,—May I beg a little space in which to put forward a plea or reasonable toleration in this matter of artificial insemina- ion? It seems to me regrettable that all the old arguments that ave been used down the ages against any innovation in edicine should again have to be disinterred. Substitute naesthesia for artificial insemination in these letters of righteous ndignation and we resurrect the ghost of the furore that was reated when ether was first introduced. Can we not take a ore rational view without undermining the true Christian alues and sanctity of married life?

We can all agree that the childless marriage is a hollow hing—a plant which has wilted and produced no fruit. Those any unfortunate couples placed in this predicament must per- orce seek some substitute for the emptiness that cannot be illed by the fruits of their love. Adoption has hitherto been the ost widely practised substitute. It has obvious disadvantages, ot the least of which is the frequently poor genetic quality of he material presented for adoption. Artificial insemination ffers an alternative to adoption which has both advantages and isadvantages. Mother and child have the advantage of a hysical basis to their relationship; all three partners have to ace the fact of the substitute father. Obviously some couples an easily adjust to this situation where others might find it mpossible.

Those critics who accuse the woman of adultery, it seems to e, confuse the letter of the law with the spirit. They see no ifference between the intimacies of the bed-chamber and the ractices of the laboratory. Can we not allow each couple to ecide for themselves and allow them the privilege of decent otives in the seeking of a solution to their very tragic dilemma? urely it is hardly the physician's role to set himself up in oral judgment in such cases.—I am, etc.,

Chipping Ongar, Essex. F. E. S. HATFIELD.

SIR,—The correspondence in your columns regarding artificial nsemination illustrates the reluctance of even the scientifically inded to lift the blankets heaped upon procreational matters y religion, convention, upbringing, and kindred influences in rder to examine that human cauldron in the cold light of cience and reason.

Without entering into the merits of the case, for or against, t may be said that the subject is a facet of a problem which ooner or later humanity will have to resolve—namely, how to ive effect to the influence of heredity and breeding in the nterests of the improvement of the race. The prime emphasis laced by Nature on this essential is self-evident in every form f life; yet by man for men, and by men alone, it is ignored nd even combated. The problem is one of especial concern nd urgency to democracies, such as our own, where if the resent trend towards quantity rather than quality continues here is danger of racial degeneration and subsequent extinction y reason of their own liberal doctrines. We are taught that ll men are equal in the sight of God; hence we continue to reed any and every sort of rubbish, and call it His will and His work. If mankind gave as much attention to the breeding f men as they do to that of other forms of life, or even to the roduction, let us say, of the perfect motor-car, it might well e that the "kingdom of God on earth" would be advanced y thousands, perhaps millions, of years.—I am, etc.,

Wicksworth, Derbyshire. E. D. BROSTER.

Tapeworm in Freshwater Fish

SIR,—In the *Journal* for Feb. 10 (p. 199) Mr. T. E. Gibson eported finding in the peritoneal cavity of a trout 39 lerocercoids, which showed morphological characters similar o those described by Duguid and Sheppard (*J. Path. Bact.*, 1944, 56, 73). The trout had been caught on Sept. 24 in a Northamp- onshire reservoir, from which six dead trout had been picked p between Aug. 11 and 25. "During the period when deaths were being observed in the trout fifty grebe also died, but it is ot known whether or not the dead grebe were infected with *Diphyllobothrium*."

I examined an adult male great-crested grebe, *Podiceps cristatus*, which had been found dead on Aug. 16 on the same reservoir. The grebe was very emaciated and anaemic, with oedema of the lungs, subcutaneous and intermuscular tissues. The small intestine was acutely inflamed and very much distended by a cylindrical mass of eighty-two intertwined tapeworms; *Ligula intestinalis* (Léon, 1758), which were mostly immature, though one or two showed signs of adult features. The heads and necks of three of the *Ligula* had burrowed under the cuticular lining of the gizzard, the lumen of which contained a felted mass of grebe feathers mixed with shreds of water plant. The small intestine also contained some very small cestodes, which were too decomposed for identification; some small trematodes, *Petasiger neocomense* (Fuhrmann, 1927); and two female nematodes, possibly *Contracaecum ovale* (Linstow, 1907). I am indebted to Dr. H. A. Baylis for kindly identifying these worms.

Later I was informed by the manager that on Aug. 12 a number of grebes, believed to be native to the reservoir, seemed listless and off their food. Eighteen of them were picked up dead on Aug. 14. By Aug. 21 a total of forty-nine dead grebes had been found. Of the other species of birds on or around the reservoir (e.g., mallard, teal, lapwings) none appeared to be affected. Between Aug. 12 and 21 "some fish, mostly trout, about 3 to 4 lb. in weight, also died, most of them in bad condition. No careful examination was made of the trout, but a roach was seen with tapeworms in it." The reservoir, completed and filled 4 years previously, was shallow owing to drought. At the beginning of August the temperature of the water rose; on Aug. 17 it was 69° F. and on Aug. 21 it dropped sharply, after which date no more dead birds were picked up and the few surviving grebes appeared to have recovered.

I was impressed by the severity of the enteritis which *Ligula intestinalis* is capable of producing when examining a goosander drake, *Mergus merganser*, which had been found dead on a freshwater lake in October, 1935. Beyond a single trematode, possibly *Diplostomum parviventosum* (Dubois, 1932), the duodenum contained two adult *Ligula intestinalis* (Léon, 1758), which had produced acute haemorrhagic ulcerative duodenitis with secondary acute septic peritonitis.

From Bruno Hoffer's *Handbuch der Fischkrankheiten* (Stuttgart, 1906), Sprehn's *Lehrbuch der Helminthologie* (Berlin, 1932), and H. A. Baylis (*Vet. Rec.*, 1934, **14**, 1472) I gather that the first intermediate hosts of the ciliated hexacanth *Ligula* embryo are freshwater Copepods (*Cyclops and Diaptomus*). The second intermediate hosts (of the plerocercoid) are various freshwater fish, chiefly Cyprinidae. The final hosts have been identified as freshwater fish (carp, tench), and several species of birds which eat freshwater fish (divers, grebes, gulls, terns, herons, eagles, hooded crows, etc.). In order to clear up the identity of Mr. Gibson's plerocercoids I would suggest that they be fed to final-host birds. Even the domestic duck might well serve for such a repeat of Duchamp's experiments (1876) as referred to by T. S. Cobbold (*Parasites*, etc.; London, 1879). According to Cobbold the *Ligula* of the final-host fish do not attain sexual maturity. The sexually immature was termed (*vide* Hoffer) *Ligula simplicissima* (Rud., 1802), now, as Dr. Baylis kindly informs me, generally regarded as synonym of *L. intestinalis* (L., 1758). Thus by feeding the plerocercoids to goldfish Mr. Gibson could produce adult *Ligula* (if they are *Ligula*) more easily under laboratory conditions, but they would not enable him to complete the whole cycle of development. The duck appears to be the experimental host of choice.—I am, etc.,

London. TOM HARE.

Wilkinson's Ointment

SIR,—In the obituary of Dr. A. T. Wilkinson (Feb. 10, p. 201) your contributor remarks: "One-prescription of his had a curiously wide European reputation," basing this conclusion on the fact that some Manchester medical workers with the Russian Army in the last war "found that scabies was treated with what the Russians called Wilkinson's ointment, the formula of which was equal parts of sulphur and ammoniated mercury ointments and of benzoated lard. . . ."

I am loath to detract from the credit due to this distinguished physician, but suspect that some confusion may have arisen.

The preparation known as Wilkinson's ointment has indeed been very widely used on the Continent, especially Central Europe, for scabies and various chronic skin affections for a very long time, probably about 100 years. The American dictionaries of Dorland and of Stedman agree in ascribing it to *J. H.* Wilkinson, "English physician of the 19th century," and they both state that it is the compound sulphur ointment of their national formulary, and this is identical with ung. sulphuris co. *B.P.C.*—namely, sublimed sulphur 15 g., calcium carbonate 10 g., tar 15 g., lard 30 g., soft soap 30 g.

In the 1923 edition of the *B.P.C.* the synonyms of ung. sulphuris co. are given as Wilkinson's ointment and unguentum ad scabiem viennense. The *Extra Pharmacopoeia* gives Wilkinson's ointment as a synonym of ung. picis et sulphuris, a London Hospital formula of very similar composition. Volk and Winter's *Lexikon der Kosmetischen Praxis* (1936, Vienna: Springer) says it is a tar–sulphur ointment, and that "it is now mostly used in Hebra's modification as Hebra-Wilkinsonsche Salbe" as follows: cretae albae 5.0, sulfur. praecip. 7.5, ol. rusci 7.5, sapon. kalin., adip. suill. āā 15.0. They give as the "old prescription": cretae 8.0, flor. sulf. 12.0, ol. fagi 12.0, sapon. kalin. 24.0, adip. suill. 24.0. This implies that a Wilkinson's ointment with the latter formula was an established remedy in Hebra's day (1816–1880). It will be seen that at Hebra's death Dr. A. T. Wilkinson would have been only 27.

All these formulae agree in containing tar, sulphur, and soap. If, therefore, the Russians were really using a mixture of sulphur and ammoniated mercury ointment and benzoinated lard, it may be that this was a formula devised by Dr. A. T. Wilkinson. It is, however, unlikely that, mainly for the same disorder and under the same name, two ointments with different formulae, invented by different Wilkinsons, should have been widely used abroad.—I am, etc.,

London, W.1. W. N. GOLDSMITH.

Breathing and Coronary Circulation

SIR,—In your issue of Feb. 24 you included a letter from Dr. R. Halstead Dixon under the heading "Breathing and Coronary Circulation." In the text of this letter Dr. Dixon has inserted in the manner of a parenthesis a reference to one of Mr. F. Matthias Alexander's books, *Constructive Conscious Control of the Individual*, and both the substance of his reference *and* the subject-matter to which it is set in relation in the text give an entirely misleading conception of Mr. Alexander's work. In sending you his letter Dr. Dixon may have been motivated by the desire to do a service to work which has attracted his interest and to help his fellow practitioners and others; and you may have been motivated by similar desires in accepting his letter; but your combined actions, which have been based upon misconceptions and misunderstanding, have resulted in disservice to all your readers. Alexander's work deals with demonstrable truth, and no amount of misrepresentation can destroy it, for truth will out; but misrepresentation may delay its spread and hinder its application when and where it is most needed.

On Jan. 28 I submitted a letter to you under the heading "The 'Psychosomatic' Approach," which letter you rejected upon the grounds of lack of space. I sent a copy of my letter to Mr. Alexander, who replied that it was "excellent"—an expression which when used by him indicates that the subject-matter is founded upon a reliable conception of his work. Mr. Alexander's work deals with the re-education of defective sensory appreciation which is the means whereby misconceptions and misunderstanding are reached, and his work also deals with the manner of use of the self which is the means whereby all the actions—including "medical" actions—are conceived and guided.—I am, etc.,

Bolton, Lancs. MUNGO DOUGLAS, M.B., CH.B.

SIR,—Since my letter under this heading appeared on Feb. 24 Mr. F. Matthias Alexander has been in communication with me. I regret that he was misinterpreted, for which I apologize.—I am, etc.,

Ealing, W.5. R. HALSTEAD DIXON.

GIFT BY AMERICAN ANAESTHETISTS

In return for the hospitality which during the last two and a half years anaesthetists in the United States Forces passing through London have received from the Royal Society of Medicine, the American Society of Anaesthetists has presented for installation in the Barnes Hall at 1, Wimpole Street a 16-mm. cinematograph projector for sound and picture. The presentation was made on March 2 by Col. R. M. Tovell, U.S.A.M.C., who spoke of the appreciation of himself and his colleagues of the opportunity they had been given of listening to British medical men of renown and of making many valuable friendships. The gift was received by Dr. Frankis Evans president of the Section of Anaesthetics of the Society, with some appropriate words concerning the understanding and good fellowship which it commemorated. In his turn he handed over the apparatus to the President of the Society, Surg. Rear-Adml. Gordon-Taylor, for the use of the R.S.M. in general In accepting the gift Admiral Gordon-Taylor remarked on the contribution which American anaesthetists had made to the advancement of anaesthesia. A century ago Wells and Colton of Connecticut did pioneer work with nitrous oxide, while from Morton and the Massachusetts General Hospital came ether anaesthesia. Thirty years ago Gwathmey of Chicago introduced—or perhaps reintroduced, for it was first essayed by Pirogov, the great Russian surgeon, in 1847—the rectal channel for ether administration. He added that the charming generosity and liberality of the medical profession in the United States were well known to many of them, and he from personal experience, both as an individual and in a representative capacity, could testify to it. It was customary to raise monuments in stone or bronze to the honoured dead, but this gift was no barren or silent symbol; rather was it an eloquent and rhythmical reminder of a "lively anaesthetic entente," and, in a wider sense, of the faith and friendship and mutual sacrifice of the two great English-speaking peoples. They all trusted that this growing understanding between the two countries would be, not a temporary liaison, but a perpetual friendship.

The Services

The following appointment, awards, and mentions have been announced in recognition of gallant and distinguished services in the field:

M.B.E. (Military Division).—Capt. J. H. D. Millar, R.A.M.C.

M.C.—Capts. A. D. McKenzie, C. A. Richardson, and K. A. C Clarke; Lieut. J. G. Des Biens, R.C.A.M.C.

Mentioned in Dispatches.—Major (Temp.) R. Stuppel (killed in action) and Capt. D. B. Watson, R.A.M.C.

The following awards have been announced in recognition o gallant and distinguished services in North-West Europe:

Second Bar to the D.S.O.—Brig. (Temp.) H. L. G. Hughes C.B.E., D.S.O., M.C., R.A.M.C.

M.C.—Capt. (Temp. Major) W. J. Hay; Capts. G. M. Killpack G. P. Mitchell, H. N. Smith, J. M. Willcox; Lieuts. F. Hartley and W. M. Walker, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Killed in action in Burma.—Capt. Archibald Menzies Ogilvie R.A.M.C.

DEATHS IN THE SERVICES

The death has been announced of Col. JOHN CRIMMIN, V.C. C.B., C.I.E., I.M.S.(ret.), at Wells, Somerset, at the age of 85. H qualified in Dublin in 1882 and subsequently took the D.P.H He entered the Indian Medical Service in 1882 and distinguished himself during the Burma campaign of 1886–8, and when S.M.O. o the Karen Field Force during the forcing of the Nanko Defile h gained, in 1889, the first Victoria Cross to be awarded to an I.M.S officer. Later he entered the Bombay Medical Service and was por health officer of Bombay for a number of years and became wel known to many I.M.S. officers embarking for leave home as a genial Irishman. In 1901 he was awarded the C.I.E. During the war o 1914–18 he served on the North-West Frontier of India and becam Assistant Director of Medical Services, India. He received the C.B in 1913, was Honorary Physician to the King 1916–19, and retire in the latter year. Col. Crimmin resided for a time at Croydon but later moved to Somerset. He thus had a varied and distin guished career and will long be remembered by his many friends He was married and had two sons.

Obituary

D. CHARLES WELSH, M.B., CH.B.

The death took place very suddenly on Feb. 20 at Kippford in the Stewartry of Kirkcudbright of Dr. David Charles Welsh, who had retired from practice in Castle Douglas in June, 1944, after 40 years of active work in that town. He was born in 1880 at Innerleithan, graduated M.B., Ch.B. at Edinburgh in 1903 and began practice in Castle Douglas. He served with the R.A.M.C. in the last war from 1915 until the end, retiring with the rank of captain. Medico-political matters were of particular interest to him. As a member of the B.M.A. he completed two terms of office as chairman of the Dumfries and Galloway Division and later was elected president of the Border Counties Branch of the Association. The Castle Douglas Cottage Hospital was very near to his heart and benefited by his services, as it was through his untiring efforts that a very efficient *x*-ray plant was introduced and was operated by him as honorary radiologist until his retirement. In public work Dr. Welsh gave valued service to the community, being co-opted a member to the Castle Douglas Town Council in 1910 and at the next election was returned at the top of the poll, subsequently becoming Provost in 1912. At the time of his election he was the youngest Provost in Scotland. A member of the Scottish Episcopal Church, he was one of the Vestry of St. Ninian's Church, Castle Douglas, and, having considerable musical talent, frequently acted as organist. His public service also included the offices of vice-chairman of the Stewartry Branch of the St. Andrew's Ambulance Association, membership of the Castle Douglas Nursing Association, the Stewartry Insurance Committee, and local medical and panel committees. Dr. Welsh had a most kindly and sympathetic nature and was regarded with much affection by his patients, who duly appreciated his skill and unvarying attention. To his colleagues in the district he was a much-valued friend and gave unsparingly of his kindly help, which was often sought by them.

Dr. Welsh's death (writes A. C.) has profoundly affected a wide circle of patients and friends who had hoped he would regain the health and vigour which he had sacrificed in ungrudging service. Within a few years of coming to Castle Douglas he had entered into partnership with Dr. Robert Lorraine, an association which continued for nearly 40 years. The practice was an extensive one and Dr. Welsh gave unsparingly of his wide knowledge and experience. He was the "family doctor" in the highest sense of the term. His interests were many. Three stand out. He was particularly concerned with the Cottage Hospital and was the driving force in its development. He spared no pains in his successful efforts to keep it up to date, and he was responsible for both the installation and the working of its *x*-ray department. He was an enthusiastic member of the B.M.A., and his presidential address to the Border Counties Branch on "The Subcutaneous Injection of Oxygen and Carbon Dioxide" was published in the *B.M.J.* in 1932. His wise counsel in various committees was highly valued. The Voluntary Aid Detachment of the Red Cross found a very warm place in his heart. He was lecturer to the local branch from its inception in 1911 until his retirement, and he twice had the pleasure of seeing his team win the Caledonian Shield. His relaxations were few, but perhaps he most enjoyed being afloat on the Solway at the helm of his yacht, preferably with a few privileged passengers. His fishing-rod, too, was a loved companion. Fearless and outspoken, his sincerity and charm of manner always successfully coated the pill. The Stewartry of Kirkcudbright has suffered a loss that is irreparable. To Mrs. Welsh and her three daughters sincere sympathy is extended from a host of friends who held him dear and appreciated his sterling worth.

ALEXANDER FORBES, M.B., C.M.

Alexander Forbes, who died at Sheffield on Feb. 7, at the age of 80, was a man of more than local importance. He was one of the most influential general practitioners in the country. An Aberdonian, educated at the local Grammar School and University, he was rather late in qualifying. One reason was that during his student career he learned one day that a famous Peterhead whaler, the *Eclipse*, was delayed in port because the surgeon had been taken seriously ill; on the spur of the moment he shipped as surgeon.

In 1890 he took his M.B., C.M. and came to Sheffield, where he set up in general practice. He soon built up a large practice and won a seat on the City Council as a Conservative. After three years he did not seek re-election because he found the duties too time-consuming. He was the first advocate in Sheffield of meals for school-children. Although a member of the B.M.A. from 1892, it was not until the fight about the Insurance Act that he gained a great local reputation as a leader of the profession. The fight was lost, and the feeling in the profession was very bitter indeed, but Forbes was the heart and soul of a party of practitioners who determined to make the best of things and to try to get the best possible medical service for the city. He became chairman of the Panel Committee, whilst one of his old political opponents, the late Mr. Arthur Neal, became chairman of the Insurance Committee. Forbes could always appreciate the legal point of view and Neal the medical point of view; to the present writer the co-operation of two such political opponents has always appeared to be a shining example of what municipal politics ought to be. Forbes combined his local work, which was extremely onerous, with a seat on the Council of the B.M.A. and on the Insurance Acts Committee. He was also much in request as a member of or medical assessor to many of the tribunals and committees which were continually instituted to settle problems arising on range of service, prescribing, etc., and in this way played a great part in setting up the kind of "case law" which governs the administration of the Insurance Acts. His notably judicial mind was of the greatest service on these bodies. He was also for some time a member of the West Riding Panel Committee and various liaison committees and subcommittees which served to unite the profession in Yorkshire. For some years Forbes and Hillman of Wakefield served their profession together in Yorkshire and in London, and will be remembered together. Forbes was a regular attendant at Annual Meetings, being Representative of Sheffield on eight occasions.

Besides his work for the Sheffield Division of the B.M.A. Forbes held office as vice-president of the Section of Industrial Diseases at the Sheffield Annual Meeting in 1908, as secretary of the Section of Medical Sociology at Glasgow in 1922, and as vice-president of the Section of Medical Sociology at Portsmouth in 1923; he had also served on the Central Ethical Committee of the Association and several subcommittees. He represented the Local Medical Committee on the Court of Management of the Royal Sheffield Infirmary and Hospital, and was a member of the Onslow Committee on Hospitals.

He was a man of very alert mind and he retained his alertness to the end. Thus in 1938 he attended a postgraduate course at a Northern city and brought back to Sheffield a wonderfully detailed account of what had been taught there. He could pick up a new medical doctrine or get the gist of new knowledge in a remarkable manner. He took a very lively interest in Sheffield University, and was a leading spirit in the movement which resulted in the Panel Committee making a voluntary grant of £1,000 to the University for the equipment of its (then) new department of pharmacology. What was the chief characteristic by which we shall remember him? Certainly his unfailing kindness! During two wars, and during the intervening period, puzzled and anxious practitioners have taken their problems to him and have received advice and help. Censoriousness and righteous indignation had no part in his make-up, so he made no enemies in a long career during which he was often engaged in controversy. A. E. B.

The death occurred at his residence in Kingsmere Avenue, Belfast, on Feb. 4 of Dr. WILLIAM ROBERT HAYDEN. Born in 1872, he qualified as M.B., Ch.B., B.A.O. of the old Royal University of Ireland in 1905, and proceeded to the M.D. degree four years later. For almost forty years he was engaged in general practice in the Cliftonville district of Belfast, and gained for himself an enduring place in the affection of very many people. The fact that he himself had to bear the burden of a chronic disability seemed to make him the more anxious to bear the burdens of others, and to increase his sympathy for the sick and his understanding of the problems of disease. Modest and unassuming, he was a sound diagnostician, an accurate observer, and keenly interested in each new development of medical treatment. During the air raids of

1941. many hundreds of houses in his neighbourhood were destroyed, and he rendered magnificent service to the injured with a fine disregard of his own safety. Dr. Hayden is survived by his widow, two daughters, and a son, Dr. Ernest Hayden.—R. M.

It is now known that Dr. **Arthur Clement Stamberg**, O.B.E., of St. Helier, died in Jersey on Aug. 19, 1944. He had studied medicine in Edinburgh, London, Dublin, and Vienna, and graduated M.B., C.M.Ed. in 1892, after which he served as clinical assistant at the Royal Westminster Ophthalmic Hospital and as aural assistant at the Central London Throat Hospital. He joined the British Medical Association in 1894 and was a member of the British Institute of Radiology and of the Ophthalmological Society. He served with the R.A.M.C. in the last war and reached the rank of lieut.-colonel, and later was Deputy Commissioner for Medical Services under the Ministry of Pensions for the Channel Isles area. Dr. Stamberg published notes in these columns on ophthalmological subjects and also, in 1922, a paper "The Pensioner: A Clinical Study," when he was president of the Southern Branch of the B.M.A.

Dr. **John Robert Summers Park**, who had been part-time M.O.H. for Dukinfield for 38 years, died in retirement on Feb. 16 at Romiley, Cheshire, aged 84. He studied medicine at Owens College, Manchester, and St. Thomas's Hospital, qualifying L.R.C.P.&S.Ed. and L.R.F.P.S.Glas. in 1887. He started his professional career at Dukinfield in the following year, and in 1892 was appointed M.O.H. to the old local board. When Dr. Parks retired from public service at the end of 1930 the death rate in Dukinfield had fallen by 50%, the infant mortality was the lowest of any town in Cheshire, and the sanitary organization was beyond reproach. Tributes to Dr. Park's valuable work were paid by the Health Committee and by the Town Council in public session, and he received a presentation at a dinner in the town hall. He was for many years a member of the visiting staff of the Ashton and District Infirmary and the Children's Hospital, had been president of the Ashton-under-Lyne District Medical Society, and chairman of the local Division of the B.M.A. Dr. Park was a J.P. for Cheshire and an officer of the Order of St. John of Jerusalem.

Dr. **Benjamin Hugh Nicholson**, late of Colchester, died suddenly at Lynwood on Feb. 19 aged 85. He graduated M.B., C.M. of the University of Edinburgh in 1884 and followed this with postgraduate study in Vienna. He was for many years surgeon to the Essex County Hospital, becoming the senior member of the staff, and had been medical officer to the Post Office and the Orphans' Home, honorary surgeon to the Fire Brigade, and medical examiner for the Education Department; he also acted as medical referee for Colchester and District under the Ministry of Pensions. Dr. Nicholson joined the B.M.A. in 1896, served on the Central Council in 1908–9 and 1911–12, and represented his Division at the Annual Meeting at Swansea in 1903.

Dr. **Frederick Augustus Sharpe**, medical officer of health for Preston, died at Longton on Feb. 21. He was born in Leicestershire in 1881, and from Guy's Hospital graduated M.B., B.S.Lond. in 1905. He proceeded to the M.D. in State Medicine in 1910 and took the D.P.H. of Leeds. Deciding to make his career in the Public Health Service he became resident medical officer at Monsall Fever Hospital and assistant M.O.H. for Derby. In 1911 he was appointed M.O.H. for Chesterfield, and after four years there moved to Barnsley. He took up his duties as M.O.H., school medical officer, and tuberculosis medical officer for the county borough of Preston in 1920. Dr. Sharpe had been a member of the B.M.A. since 1909, and contributed to these columns on Oct. 24, 1924, a report on an unrecognized outbreak of smallpox in a community where the only control was the previous partial vaccination of the contacts and the fact that it occurred in institutions under discipline and observation. A colleague writes: The tragically sudden death of Frederick Augustus Sharpe at the age of 63 came as a great shock to his many medical friends. Only the previous day he had carried out his official duties apparently in his usual health. A native of Sileby, Leicestershire, he was educated at Loughborough and Chesterfield Grammar Schools and at Guy's. He was an ex-president of the North-Western Branch of the Society of Medical Officers of Health, and sometime member of the council of that society. In his work he was conspicuous for high administrative ability and for the soundness of his judgment. The outbreak of war imposed heavy burdens upon him and it was his task to establish the medical services in connexion with civil defence. Here his powers of organization found ample scope. His sense of loyalty, his geniality, and his ready wit were characteristics which endeared him to his friends and colleagues. The loss of his elder son, Capt. R. M. Sharpe, R.A.M.C., who was killed in action in 1943, was a grievous blow to him, but he bore it with calm fortitude. He is survived by his wife, a son serving abroad in the Royal Corps of Signals, and a daughter who is a bacteriologist. To them we extend our deep sympathy.

We regret to announce the death on Feb. 22, at the early age of 38, of Dr. **Norman Lloyd Price** of Clifton, lecturer on diseases of children in the University of Bristol, and honorary physician to out-patients at the Bristol Children's Hospital. He studied medicine at Bristol, took the English Conjoint diplomas and the M.B., Ch.B. degrees of his university in 1929, proceeded M.D. in 1934, and became M.R.C.P. in 1936. After serving as house-physician and casualty officer at the Bristol General Hospital he worked for a time as deputy medical superintendent of the Southmead Hospital, Westbury-on-Trym, and in addition to his other hospital posts was consulting physician to the Stoke Park Colony. Dr. Lloyd Price was a member of the council of the Section of Disease in Children of the Royal Society of Medicine and had published papers in the *Lancet* and the *British Journal of Surgery*. He joined the B.M.A. in 1930 and was an active member of the Bristol Medico-Chirurgical Society.

Dr. **Edward Percival Dickin**, for 33 years M.O.H. of Brightlingsea, Essex, died on Feb. 25. He studied medicine in Edinburgh and Paris, and at the Middlesex Hospital, graduated M.B., C.M.Ed. in 1893, and proceeded M.D. in 1899 after taking also the English Conjoint diplomas. Before settling in practice at Brightlingsea he had been house-surgeon at the Northampton General Hospital. He served during the last war with the rank of captain, R.A.M.C., as officer-in-charge of the medical division of a military general hospital in Malta, and for some years he examined in first aid for the British Red Cross Society. Dr. Dickin joined the B.M.A. in 1896, held office as chairman of the North-East Essex Division in 1930–2, and in 1936 was elected president of the Essex Branch. When he retired from the post of M.O.H. in 1933 he received from past and present members and officers of the Brightlingsea Urban District Council an inscribed silver salver, and public tributes were paid to his long and able services to the town and his devotion to his private patients. He was a Fellow of the Society of Antiquaries and published five years ago *A History of Brightlingsea: a Member of the Cinque Ports.*

To the distress of his friends and relations Dr. **Charles Macdonell Anderson** passed away at the age of 78. Dr. Anderson was born in India, the son of a colonel in the Royal Engineers who had been through the siege of the Residency at Lucknow. He was also the nephew of another Mutiny hero, Sir James Outram. He entered Edinburgh University, where he graduated in 1889; he then came to the London Hospital and took the M.R.C.S., L.R.C.P. in 1892. Like many others of his time he went abroad for postgraduate study at Vienna and Dresden. He graduated M.D. in 1896. and was assistant in the ear, nose, and throat wards of the Edinburgh Royal Infirmary. Coming south Dr. Anderson settled and practised for nine years in Faversham before moving to South Kensington, where he spent the rest of his life. He rapidly acquired a fashionable practice. During the last war he was in charge of the Lady Mary Maynell Hospital for Officers and the Red Cross Hospital, Grosvenor Gardens. He was mentioned twice in dispatches. Though failing in health he worked all through the "blitz" days. He was a man of sound judgment and even temper, never ruffled or put out in the most trying circumstances. He was a most likeable man with a large circle of friends. He will long be remembered as an excellent physician and a delightful friend.—D. C. L. F.

Dr. **Edward Stanley Robinson** (writes a correspondent) began practice in Stourport-on-Severn, Worcestershire, in 1893, and became one of the leading general practitioners in the county. He was in every way an ideal family doctor. His professional ability was of a very high order, and he was untiring in his devotion to his patients. His outstanding characteristic was his humanity and kindness, and he was equally beloved in the mansion or the humblest cottage. As medical officer of health for Stourport, a position he held for over 40 years, he was fearless and outspoken in his efforts for the improvement of the housing of the inhabitants and the general sanitary condition of the district. He took a keen interest in all matters affecting the medical profession, and was a very regular attendant at meetings, at which his remarks were always practical and moderate.

Surgeons who carried out research at the Buckston Browne Farm at Downe will learn with regret that Mr. E. J. Smith, the custodian of the Farmhouse, died on Feb. 23 in Farnborough Hospital, Kent, from cancer of the lung at the age of 55. He entered the service of the Royal College of Surgeons as college messenger in 1908 at the age of 18, later becoming an attendant in the museum of the College. He served through the war of 1914–18, and on demobilization was placed in charge of Room I, and thus had the care of anatomical preparations, osteological specimens, and a vast collection of human skulls, ancient and modern. He became a master of skull-craft, learned how to reconstruct and delineate the most crushed specimens. It was he who chiselled out of the solid rock the fragile fossil bones of the Mount Carmel child. Geologists and others brought fossil bones for identification; Smith ran them to their source with the intuition and acumen of a Sherlock Holmes. On the opening of the laboratories at Downe in 1932, the Council of the College appointed Smith to the custodianship of the Farmhouse, while Mrs. Smith was made its housekeeper. He entered the service of the College when William Pearson was prosector, the third generation of the Pearson family to devote its skill and loyalty to its service. Smith absorbed and continued the Pearsonian tradition. Although born and bred a Londoner, he took most kindly to village life and earned the respect of all he came in contact with by his modesty, reticence, and quiet intelligence. A service to his memory was conducted in the church of Downe on Tuesday, Feb. 27, and was attended by representatives from the College.—A. K.

The following well-known medical men have died abroad: Dr. James Addison Babbitt, emeritus professor in oto-laryngology at the University of Pennsylvania, aged 74; Dr. Jean Louis Faure, formerly secretary-general of the French Society of Surgery, aged 81; Dr. Graeme Monroe Hammond, emeritus professor of neurology and psychiatry at the New York Postgraduate Medical School and Hospital, Columbia University, aged 86; Prof. Fritz Seiler, formerly director of the Medical University Polyclinic of Berne, aged 69; Dr. William Thornwall Davis, consultant ophthalmologist to the Surgeon-General of the United States Army, aged 67; Dr. Nicolas Bendia, co-founder of the Colombia Red Cross and professor in the Bogota faculty of obstetrics, aged 75; and Dr. Max Bergmann, biochemist, member of the Rockefeller Institute for Medical Research, aged 58.

Medical Notes in Parliament

Child Immunization in Glasgow

On Feb. 20 Mr. Westwood informed Major Lloyd that the medical officer of health for Glasgow estimated that of the children of school age and pre-school age in Glasgow at Dec. 31, 1943, the percentages immunized against diphtheria were 60 and 23 respectively. Major Lloyd asked if the Minister would receive a deputation from the medical profession in Glasgow to discuss ways and means of improving the position. Mr. Westwood replied that the Minister was always willing to meet deputations prepared to put any case before him to improve health conditions of Scotland.

Foot-and-Mouth Disease Infection

On Feb. 20 Major Braithwaite asked the Minister of Agriculture whether, in view of the fact that the principal source of infection causing outbreaks of foot-and-mouth disease in this country was imported meat, and to provide guarantees against the sale of such diseased meat to the public, he would undertake, after giving due warning, that in future the import of meat would be prohibited from any country which had not taken satisfactory steps to eradicate this disease. Mr. Hudson said he had consulted the Minister of Health and the Minister of Food on this matter. He was advised that there was no evidence of danger to human health from the importation into this country of carcases from the countries in which foot-and-mouth disease occurred, although there was a serious danger to our own farm animals if they were allowed to come into contact with meat which might be infected. There would be difficulty about adopting the course proposed in the question at present.

Contributory Negligence in Cases against Doctors

Sir David Maxwell-Fyfe on Feb. 22 moved the second reading of the Law Reform (Contributory Negligence) Bill. The Bill, which has already passed through the House of Lords, would apply to accidents on land the Admiralty rule that if the person suing had contributed to the negligence he would still have a right to a proportion of the damages which he would have recovered if entirely free from blame.

Dr. Russell Thomas asked what would happen, under the Bill, in actions against professional men, such as actions against doctors for malpractice. Such actions now frequently failed. Many were brought on the off-chance of getting damages, or from malice. He had investigated a series brought during 30 or 40 years against doctors and found that in very few cases did the plaintiff succeed. Often the court condemned the plaintiff for bringing the action. The Bill would tend to increase the number of such actions. It would be easy to come to court and endeavour to show some degree of negligence. On the other hand the professional man could no longer win his case by alleging contributory negligence in the patient's application of treatment. Mr. Glenvill Hall said that if in the past doctors had been guilty of negligence and had got away with it, it was time the "racket" was stopped.

Sir David Maxwell-Fyfe said that in actions against professional men the question of contributory negligence seldom arose. The issue was whether there had been negligence or breach of duty on the part of the professional man. That took a deal of establishing, and there were few successful cases. He could not see that the professional defendant would be prejudiced in any way by the Bill.

The Bill was read a second time.

The Nation's Water Supply

On the motion of Mr. Willink the House of Commons on Feb. 21 read the Water Bill a second time. Mr. Willink said one of the purposes of the Bill was to provide an up-to-date substitute for the Waterworks Clauses Act of 1847, commonly known as the "Waterworks Code." Until now there had been no general revision of that code. This Bill gave powers to secure, by compulsion if needed, a combination of water undertakings. These were far too numerous. The Bill also tightened the provisions against pollution of water. Much of the national health was due to the work of the water undertakers in providing safe and ample supplies in the great towns. The nation was free from cholera and almost completely free in recent decades from typhoid. Between the wars the number of houses in the country without piped supplies had been halved, but one-third in the countryside still lacked such a supply.

Mr. Wootton-Davies remarked that there was no definition of pure or wholesome water. A dangerous chemical, chlorine, was to-day put into the water everywhere. He believed the practice was first to put in ammonia and then to neutralize that with chlorine. Had the Minister investigated the effect of those chemicals on lead pipes and brass taps? The Bill allowed wells to be sunk to depths less than 50 feet. Such wells merely tapped surface drainage and were a danger. He suspected that arsenical sheep-dips eventually got into the water supply. He suggested that the Minister should take powers to enforce the softening of water at the source. Mr. R. C. Morrison asked the Minister to make the sealing off of disused wells obligatory. Under the present law a well could be abandoned and left with all the slime running back into the underground water.

Committee on Children in Homes

Mr. Herbert Morrison announced on Feb. 22 the appointment by Mr. Willink, Mr. Butler, and himself of a committee on children who lacked a normal home life. The chairman is Miss Myra Curtis, principal of Newnham College, Cambridge. Other members include Dr. Somerville Hastings, chairman of the L.C.C.; Dr. J. C. Spence, professor of child health in the University of Durham; Miss S. Clement Brown, in charge of the Mental Health Course for Psychiatric Workers, London School of Economics; and Miss Lucy G. Fildes, Provisional National Council for Mental Health.

E.M.S. Hospital Expenses.—On Feb. 21 Mr. Willink told Sir E. Graham-Little that he had no evidence of a system alleged to exist in certain E.M.S. hospitals under the management of county councils whereby the steward benefited personally by keeping the expenses below a certain figure, which reduced the standard of food supplied to resident medical staff and patients. Therefore the question of action to alter this arrangement at hospitals in his jurisdiction did not arise.

Notes in Brief

Returns from local authorities at Dec. 31 last showed that 436 children in England and 112 in Wales were then awaiting institutional treatment for pulmonary or non-pulmonary tuberculosis

Universities and Colleges

UNIVERSITY OF OXFORD

David Whitteridge, B.M., B.Sc., formerly Demy of Magdalen College, has been elected to a Fellowship by special election. He is demonstrator in the University Physiological Laboratory, held a Beit Memorial Research Fellowship in 1940-1, and last year was elected Schorstein Medical Research Fellow.

UNIVERSITY OF CAMBRIDGE

The following have been approved for the degree of M.Chir.: J. M. Pullan, D. I. Williams.

UNIVERSITY OF LONDON

The title of Professor of Chemical Pathology in the University has been conferred on Dr. E. J. King in respect of the post held by him at the British Postgraduate Medical School.

University College Hospital Medical School

Two Goldsmid entrance scholarships, entitling the holders to the final course of medical study; one Goldsmid entrance exhibition, and a Filliter entrance scholarship in pathology, both entitling the holders to a reduction in the fees due for the full course of final medical study, are announced. All are tenable at University College Hospital Medical School, and entries must be received by the secretary of the medical school (University Street, London, W.C.1) by June 30. Fuller particulars may be had from the same address.

UNIVERSITY OF MANCHESTER

The Council of the University has appointed Ronald Epey Lane, M.B., F.R.C.P., to the Chair of Industrial Health in the University. The institution of the chair was made possible by a grant from the Trustees of the Nuffield Foundation.

UNIVERSITY OF EDINBURGH

The Cameron prizes in practical therapeutics for 1945 are to be awarded to Sir Alexander Fleming, in recognition of his discovery of penicillin, and Sir Howard Florey, for his work in making possible the clinical application of penicillin.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week the incidence of measles fell by 1,460, and of acute pneumonia by 243. Notifications for dysentery went up by 33, those for scarlet fever by 31, for diphtheria by 25, and for whooping-cough by 14.

The incidence of diphtheria rose slightly in the south-west and Wales. In spite of the fewer cases of measles reported, several counties showed substantial rises. In the following counties notifications dropped by the numbers indicated: Lancashire 425, Warwickshire 277, Staffordshire 236, Cheshire 221, Glamorganshire 185, London 174, Essex 169; increases were reported as follows: Yorks East Riding 184, Somerset 129, Leicestershire 122, Surrey 90. Five cases of typhoid were reported from Kent, Bridge-Blean R.D.

Dysentery notifications remain high. There were two fresh outbreaks during the week—Oxford C.B. 24, and Southampton, Petersfield R.D. 22. Only 2 cases were reported from Cornwall, where 49 were notified in the preceding week. Other large returns were Lancashire 37, London 33, Middlesex 33, Essex 22, Devonshire 18, Gloucestershire 18, Derbyshire 14, Northumberland 13, Cambridgeshire 12.

In *Scotland* dysentery notifications were 36 higher than last week, scarlet fever 17, whooping-cough 15, and diphtheria 12. The increase in dysentery was due to 16 cases in Stirling County, and a rise in Falkirk from 20 to 42. The largest of the other returns were Glasgow 24, and Edinburgh 21.

In *Eire* diphtheria notifications rose by 25. A fall of 19 cases was recorded for measles, and of 14 for scarlet fever.

In *Northern Ireland* measles notifications fell by 15, but diphtheria rose by 7.

Week Ending February 24

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,544, whooping-cough 1,539, diphtheria 457, measles 23,216, acute pneumonia 1,118, cerebrospinal fever 76, dysentery 393, paratyphoid 6, typhoid 6. Deaths from influenza in the 126 great towns numbered 51.

No. 7

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 17.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

---

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

Mr. J. Z. Young, M.A., will deliver an address on "The Structure, Degeneration, and Repair of Nerve Fibres" before the Royal Institution, 21, Albemarle Street, W., on Friday, March 16, at 5 p.m.

The Faculty of Radiologists will hold a Diagnosis Section meeting at 45, Lincoln's Inn Fields, W.C., on Friday, March 16, at 2.30 p.m., when Drs. A. S. Johnstone and R. A. Kemp Harper will open a discussion on non-malignant conditions of the oesophagus. Other radiological meetings to be held in London about that date are: British Institute of Radiology, 32, Welbeck Street, W., March 15, at 8 p.m, when Mr. L. Dudley will speak on stereoscopic photography and radiography; R.S.M., 1, Wimpole Street, W., March 16, at 6 p.m., Dr. J. Wilkie on radiology of the small intestine.

A clinical meeting of the Tuberculosis Association will be held at Brompton Hospital on Friday, March 16, at 2.30 p.m.

The exhibition of specimens, photographs, and drawings of war injuries on view to members of the medical profession in the Council Room of the Royal Society of Medicine will be extended another week, up to and including Friday, March 16.

A private business meeting of the Association of Industrial Medical Officers will be held at the London School of Hygiene, Keppel Street, W.C., on Saturday, March 24, at 11 a.m. At 2.30 p.m. there will be a discussion on "Ophthalmological Problems and Visual Standards in Industry," to be opened by Dr. W. Jeaffreson Lloyd, Mr. Joseph Minton, and Mr. T. C. Summers.

The Duchess of Kent attended her first meeting as president of the National Association for the Prevention of Tuberculosis in the Great Hall of B.M.A. House on March 1. The occasion was the inauguration of a Sanatorium Matrons' Section, and the meeting was attended by some 150 matrons of sanatoriums in all parts of the country. Her Royal Highness was received by the Duchess of Portland, chairman of council of the N.A.P.T., Dr. R. A. Young, vice-chairman, and Dr. Harley Williams, secretary-general.

Dr. A. H. G. Burton has recently completed 25 years' service as medical officer of health for the town of Ilford. At a commemorative function, attended by the Mayor and those Aldermen and Councillors who had been closely associated with the work of the department during this period, the present and former members of his staff presented Dr. Burton with a gold fountain pen and cheque. As chairman of the proceedings, Dr. J. H. Weir, the deputy M.O.H., outlined the developments of the local public health services over the past quarter of a century. He mentioned that during this time, in addition to Dr. Burton's capable organization and administration of a successful and progressive health policy, he had made valuable contributions to medical literature by the production of upwards of 20 original articles. Many other appreciative references to his work for the town were made.

The *Scotsman* records an interesting medical event in Delhi on Jan. 20. Lieut.-Gen. Sir Alexander Hood, D.G.A.M.S., Lieut.-Gen. Gordon Wilson, D.M.S. in India, and Lieut.-Gen. J. B. Hance, D.G.I.M.S., are all alumni of the Edinburgh Medical School, and their presence in Delhi at the same time prompted the holding of the first Edinburgh Medical School's alumni dinner. The attendance at the dinner—45 alumni and guests—was fully representative of Indian and British medicine. Among those present were Major-Gen. Richardson, Director of Hygiene, War Office, and Air Vice-Marshal Grant, P.M.O. Air Force in India. Brig. J. S. Fulton took the chair and proposed the health of "The King-Emperor"; Brig. J. D. S. Cameron proposed the toast of "The Guests of Honour," to which all three replied; Khan Bahadur Dr. Dahman proposed the toast of "The Edinburgh Medical School," and Brig. F. A. E. Crew responded.

The King has approved the appointment of Mr. Percy Barter to be a Senior Commissioner of the Board of Control; and the Minister of Health has appointed Mr. Barter to be chairman of the Board, on the retirement of Sir Laurence Brock from the public service on March 31. From 1930 to 1939 Mr. Barter was secretary of the Board and then became a Principal Assistant Secretary in the Ministry of Health. He was secretary to the Committee on Asylum Administration (1921–2), to the Royal Commission on Lunacy (1924–6), and to the Royal Commission on Local Government (1928–9).

By December, 1944, the American Red Cross had sent 5,000 tubes of penicillin by air express to the International Red Cross Committee in Geneva to be used for American prisoners of war held in Germany, and additional shipments of medicines and medical supplies will be made.

We announce with deep regret the death this week of Viscount Dawson of Penn, who was convalescing from a serious operation. A memoir will be published next week.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ANY QUESTIONS?

Ununited Fracture of Femur

Q.—*What is the best treatment for an ununited fracture of the neck of the femur in a man aged 78? Five days after the accident, x-ray examination showed a simple fracture of the neck near the head. Two months after this there were no signs of union. Would collosol calcium or other injections be advisable? For some time after the accident the fractured bones appeared extraordinarily mobile, but in the last three months this mobility has greatly diminished.*

A.—When it was decided that pinning of this subcapital fracture was inadvisable, and that owing to the patient's age, general condition, and hemiplegia, no initial treatment other than sandbag support was indicated, it must at the same time have been decided to accept non-union as inevitable. No matter how long simple recumbency and sandbag support is continued bony union cannot be expected. Collosol calcium injections will make no difference; no other preparation will make any difference. But although bone union cannot be hoped for, the capsular contraction and fibrosis which accounts for recent diminution of mobility will give sufficient stability for the patient to be able to walk. It is sometimes advisable to fit a walking calliper splint at first. But in view of the fact that this man has hemiplegia on the opposite side it will probably be better to get him up without any splint or support, other than perhaps a simple flannel spica bandage, and teach him to walk with crutches. Later on he may be able to discard one or both crutches and walk with sticks. Some shortening may develop and necessitate a raised shoe.

The only alternative to this is to perform a bifurcation osteotomy, cutting the femur at the trochanteric level and displacing the shaft inwards so that it lies under the head of the femur. In this way telescopic instability is controlled and the patient would be able to walk still better. This is an operation of some magnitude; it involves immobilization in a plaster spica for two or three months; and it will almost certainly be inadvisable in a patient of this age and constitution. So far as the ununited fracture is concerned, surprisingly good function is often regained without any operation: the only problem with this patient is the association of an ununited fracture of one limb with hemiplegia of the other; nevertheless he should learn to walk.

Carotid Sinus and Carotid Syncope

Q.—*What is the carotid sinus? What are the symptoms of carotid syncope?*

A.—The carotid sinus is the name given to the slight enlargement of the common carotid artery at its bifurcation into the external and internal carotids. Its action is like that of the governor on an engine, and it serves to maintain the arterial blood pressure within normal limits. It is supplied by the sinus nerve, which is a branch of the glossopharyngeal nerve. The terminals of the sinus nerve are stimulated by a rise in blood pressure in the carotid sinus, producing reflex slowing of the heart, vasodilatation, and a fall in the blood pressure. This effect can often be duplicated by manual pressure on the walls of the carotid sinus in normal subjects. To induce the reflex, Weiss and Baker (*Medicine*, 1933, **12**, 297) recommend that the patient should be lying on his back, with his head elevated and slightly overhanging a support. If the head is then turned somewhat to one side, the sinus is usually located just below the angle of the jaw, corresponding to the upper level of the thyroid cartilage. Pressure is then applied towards the spinal column for two or three seconds. As the reflex develops more markedly when the patient is in the standing or sitting posture, others recommend that the pressure should be applied with the observer behind the standing or sitting patient. The effect comes on rapidly, and in some two out of three normal subjects a depressor response of

10 to 20 seconds' duration will be elicited. This stratagem will sometimes restore a normal heart rate in paroxysmal tachycardia.

States of pathological hypersensitivity occur in which pressure on the carotid sinus induces attacks of vertigo, syncope, and even convulsions. The lightest pressure, as during shaving or buttoning a collar, may be sufficient to provoke an attack. In some of these patients small tumours have been found pressing on the sinus, and in others there has been aneurysmal dilatation of one or both sinuses. The trouble is more common in later life and with hypertension, and is not to be regarded as psychogenic. In a suspected case the effect of anaesthetization of the carotid sinus with procaine should be observed. If this abolishes the attacks, surgical denervation may be recommended. (See also a reply given in the *Journal* of March 11, 1944, p. 380.)

Puberty Menorrhagia

Q.—*A girl aged 13½ years suffers from persistent menorrhagia. Her menses, which started a year ago, are regular. What treatment is advised?*

A.—Thyroid is often useful in the treatment of puberty menorrhagia. Begin with 1 grain daily and gradually increase the dose to the point of intolerance. Thereafter give a subtoxic dose daily for three months—irrespective of the time in the menstrual cycle. This treatment can be combined with calcium lactate or gluconate, 20 to 30 grains daily, also for three months. General measures, such as regular physical exercise, attention to the bowels, iron, and vitamin C, should also be kept in mind. Corpus luteum hormone can be administered only by injection, but if thyroid does not help, then try ethisterone 5 to 10 mg. t.d.s. by mouth, for seven days premenstrually and for the first two days of menstruation. If that fails, then methyl testosterone in a similar dose might be considered. Ergot preparations sometimes control the blood loss temporarily if given during menstruation, but are unlikely to have any curative effect. In any case there should be a natural tendency to spontaneous cure as the girl gets older.

Fullers' Earth

Q.—*I understand that "fullers' earth" consists of microscopic siliceous particles, both spicules and tubules, derived from the skeletons of water-deposited diatoms, and can therefore appreciate that a toilet powder made from it can be of benefit by virtue of its absorptive effects. Quite frequently, however, fullers' earth is blended with lanoline or similar materials to produce emollient preparations. In what way could the addition of the powder enhance the effect of such ointments?*

A.—A paste differs from an ointment because an amount of powder is incorporated in it; it is therefore less occlusive and less "heating." For this reason a paste is found suitable in many conditions where the more occlusive ointment would aggravate the congested and inflamed skin.

? Cavernous Angioma

Q.—*A man aged 36 has a small tortuous clump of varicose veins over the lower third of his left sterno-mastoid. He states it has been present since childhood without symptoms; but during the past two years it has become hard and painful on several occasions, and now the pressure of his collar gives him permanent discomfort. He shows no other signs of varicosity and is in good health. What are the probable causes of this condition and what treatment is advised?*

A.—The difficulty here is one of diagnosis, which cannot be made with certainty without seeing the patient. The abnormality has been present since childhood, and is therefore probably congenital. If this is correct, the condition is more likely to be a cavernous angioma than a true varicose vein. This view is favoured by the fact that it has on several occasions become harder and painful, for this change is known to occur in angiomata. If the patient is in good health and has no other similar lesion, we cannot be dealing with varicosity compensatory to blockage of deeper veins. If this view is correct, the best treatment would be excision.

Dupuytren's Contracture

Q.—*A man developed Dupuytren's contracture in his right hand at the age of 60 to 63. First signs of the same thing were observed shortly after his 67th birthday in his left hand. They have progressed very little in the following three years. Is there any known procedure for slowing down or checking their further development? Incidentally it may be of interest to state that the man's father died at the age of 63, having what was almost certainly Dupuytren's contracture in his right hand. The father was an accountant, the son a university lecturer.*

A.—There is no known method of checking the development of Dupuytren's contracture. The condition is due to a sclerosis and thickening of the palmar fascia, particularly affecting those processes which go to the ring and middle fingers. Its cause is unknown. Trauma and chronic recurring pressure may be exciting factors, and it may occur in several members of the same family, commonly in father and son. There is no satisfactory evidence to connect it with gout. At one time subcutaneous injections of thiosinamine (allyl sulpho-carbamide) used to be given with the intent of softening the fibrous tissue, but this proved of little or no value. Wearing a corrective splint at night might possibly slow the process, but it is hardly worth trying in a man of 70, for the condition is very slowly progressive and does not usually cause much inconvenience when of minor degree.

Bovine Tuberculosis

Q.—*Is it true that the incidence of bovine tuberculosis in children is higher in England than in the U.S.A., and is it true that in Great Britain less than 10% of the herds are tuberculin-tested?*

A.—Evidence favours the view that human tuberculosis due to the bovine bacillus is less frequent in the U.S.A. than in Great Britain. This evidence is, in part, based on the opinions of authorities from the U.S.A., and in part on figures of lower incidence of such conditions as tuberculous meningitis, in which bovine infection is common. Exact comparative figures do not, however, appear to be available.

The number of herds in Great Britain which are tuberculin-tested is comparatively small and certainly far below 10%. They fall into two groups—i.e., those which are dealt with as "attested" herds and those which comply with the designation of "tuberculin-tested." The attested herds are a very small proportion of the herds in the country. The "tuberculin-tested" licences on March 31, 1943, in England numbered 3,195, and on March 31, 1944, they were 4,630. These represent figures far below 10%. For example, in Somerset and Gloucestershire, two counties which have high figures for T.T. herds, the combined T.T. licences at the end of 1944 only represented about 6% of the milk-producing herds in the county.

Air Conditions and Chronic Bronchitis

Q.—*What effects have air conditions on chronic bronchitis? Is air-conditioning any use for chronic bronchitis if the patient can remain in the conditioned air during an attack?*

A.—Atmospheric conditions have a marked effect on chronic bronchitis: the bronchial mucous membrane is atrophic and therefore unable to deal satisfactorily with changes of humidity and temperature. Cold, especially damp cold, is unfavourable, but the optimum humidity varies in different types. A rarefied atmosphere is usually unsuitable for old patients, owing to associated emphysema.

Air-conditioning is very useful if the patient is able and willing to remain in the air-conditioned rooms throughout the winter, except when the outside conditions are favourable; this is seldom the case, and so its value is limited. Great benefit was obtained by one patient with tuberculous fibrosis and associated chronic bronchitis. In exacerbations it is of value from a symptomatic point of view, but if possible the aim should be to prevent these rather than to treat them.

Adiposis Dolorosa

Q.—*A middle-aged woman suffers from adiposis dolorosa. Could you suggest anything for her treatment?*

A.—There is no certain pathological basis for adiposis dolorosa, as distinct from other forms of hypothalamic-pituitary adiposity, but clinically the special feature, as indicated by the name, is the painful character of the fatty deposits and an associated miserable depressive outlook. The treatment of the latter is along psychotherapeutic lines, as can be undertaken by an understanding family doctor, and the treatment of the adiposity is conventional—namely, low-calorie diet, thyroid to the point of tolerance, and, if there is a water-retention element, ammonium chloride and mercurial diuretics.

Toxicity of Antiseptic Dyes

Q.—*Do dye preparations such as gentian violet have the effect of aniline dyes on tissues—i.e., local tissue necrosis? Is it safe or not, for instance, to mop out a sinus with a preparation of triple dye? Presumably all such preparations are being superseded by penicillin or sulphonamide powder.*

A.—This question seems to imply that gentian violet is not an aniline dye; it is. All the antiseptic dyes have some degree of tissue toxicity. This is not gross: they do no harm to skin, and the damage they do to exposed tissues is microscopical rather than anything which can be seen with the naked eye; it can, nevertheless, be shown that individual cells, such as leucocytes, are killed or inactivated by them. Gentian violet is less toxic than brilliant green. That gentian violet can do more good than harm, at least in a certain type of lesion due to a highly susceptible organism, is shown by its dramatic effect when applied (as a 0.1% solution in 50% glycerin) in thrush. Dye preparations should be "safe" enough in a sinus. Recent clinical studies with proflavine have shown that in chronic suppuration the tissues will withstand a higher concentration than can be applied to a fresh wound. Whether this treatment will do any good depends on the nature of the infection and other factors.

Oophorectomy for Chocolate Cysts

Q.—*What is the best treatment for a patient who has had double ophorectomy for chocolate cysts and is suffering from great increase i weight with resultant lack of energy?*

A.—If it can be assumed that the lesion underlying the chocolate-yst formation was endometrioma, then replacement therapy with estrogens should be avoided, lest it reactivate any islets of endo-ietrioma remaining in the pelvis, and defeat one of the objects of the peration. The primary treatment of the obesity should be a strict iet on the usual lines, and this could with advantage be reinforced uring the initial few weeks, and thereafter periodically, by limiting ie intake of fluid and salt and giving ammonium chloride grains 10 d.s. by mouth. As regards hormone therapy, thyroid is likely to e most useful; begin with 1 grain daily, and gradually increase the ose until the patient becomes intolerant; then maintain it at a ibtoxic level. Thyroid is particularly indicated if preliminary ivestigation shows that the basal metabolic rate is significantly ecreased.

Absorption of Calcium

Q.—*It is said that calcium is not adequately absorbed from the limentary tract, and that, to be effective, it must be given intra-enously. Is this true? Is calcium of value as an adjuvant in the outine treatment of pulmonary tuberculosis?*

A.—It is quite certain that some calcium is absorbed from the limentary tract. On a normal diet the urine contains 100 to 200 mg. f calcium a day, and this may be increased two- or three-fold by high dosage of calcium salts by mouth. It is also possible that ome absorbed calcium is excreted by the bowel. Nevertheless bsorption is slow, and to secure a prompt pharmacological action, s for the relief of spasm, it is generally necessary to inject calcium ilts intravenously or intramuscularly. The slow intravenous injec-on of 5 to 20 c.cm. of 5% calcium chloride solution or 10% ilcium gluconate is often effective in relieving the abdominal pain, iarrhoea, and tenesmus of intestinal tuberculosis. Apart from this iere is no indication for calcium in the treatment of pulmonary iberculosis. For rational therapy with calcium by mouth very irge doses must be given—e.g., 5 to 15 grammes a day of the arbonate, gluconate, lactate, or phosphate—and this would seem ierely an added burden on the overworked alimentary tract of the onsumptive patient.

Dermatitis Herpetiformis

Q.—*What treatment might effect a cure in a case of dermatitis erpetiformis of 14 years' standing which apparently followed a white leg"?*

A.—Dermatitis herpetiformis is a rebellious condition, and often iils to respond to treatment, although spontaneous recovery is ossible. There is no direct connexion between "white leg" and ermatitis herpetiformis. It is assumed from the question that :senic or whole-blood injections have been tried. Sulphapyridine i small doses over a limited period has a temporary effect.

Fluorine in Toothpaste

Q.—*In a leading article on fluorine and dental caries (*JOURNAL, *pril 1, 1944, p. 461) it is suggested that fluoride might with dvantage be added to toothpaste. Does the danger of mottled namel from excess of fluorine exist only during the growing period, r does it exist at all ages?*

A.—The danger of mottled enamel from an excessive intake of uorine occurs only during the growth period, and not after the ilcification of the teeth is complete.

INCOME TAX

Appointment: Travelling Expenses

H. H. holds a main and a part-time appointment. To carry out ie duties of the latter the use of a car is necessary. The inspector f taxes has refused to allow the car expenses as a deduction for icome-tax purposes. Is this correct?

⁂ Yes. The cost of travelling to the place where the duties are erformed is not allowable if the earnings in question are chargeable tax under Schedule E. (This does not apply to travelling between vo places of employment if the expense arises out of a single ppointment.)

"Pay-as-you-Earn" Deductions

K. employs two "casual" workers—a woman cleaner and a part-me secretary. Neither of them receives remuneration amounting to)s. a week. Is he under any liability to deduct tax or report any articulars to the income-tax authorities?

⁂ No.

Deduction for Premises Owned and Occupied

"CAMFORD'S" house is rated at £105 gross and £81 net. On which amount should he calculate the deduction to be made from his profits for the professional use of the property?

⁂ The difference between the "gross" and "net" values represents the allowance for maintenance expenditure. The usual practice is to base the Schedule D deduction on the *net* value of the premises, and to claim as a further deduction the actual cost incurred from time to time on repairs, redecorations, insurance, etc., of that portion of the premises used for professional purposes. Cases may occur where by arrangement the practitioner deducts the *gross* value each year and, presumably, does not claim the actual expenditure, but such an arrangement is not legally correct nor is it likely to be satisfactory in the long run.

Cost of Assistant's Board and Lodging

J. D. has claimed £2 12s. 6d. per week as representing the cost of boarding his assistant in his own residence; the inspector of taxes considers 35s. per week adequate. Should he appeal?

⁂ It is not possible to give definite advice on a matter which depends so much on the particular facts of the case. Probably the best test is to calculate the over-all cost of running the establishment and divide it according to the number of residents—excluding the domestic staff and making any appropriate allowance for differences in quality of accommodation, etc. Unless a substantial amount of unrationed food is provided, the rationing system acts as a check on the rising expenditure on food.

Expense of Professional Course

"A1" completed a special course in hygiene and obtained a certificate which was necessary for the position he holds as assistant school medical officer. Is the expense of attending the course, etc., allowable as a deduction for income-tax purposes?

⁂ No. The courts would regard the expense as in the nature of capital outlay, the benefit from which would accrue in the future, and not as incurred in carrying out the duties of the office.

LETTERS, NOTES, ETC.

A Protective for Minor Burns

Dr. F. SUGDEN (Newbury, Berks) writes: I had an interesting experience a fortnight ago when one of the analytical chemists employed by Messrs. Suntex managed to burn his fingers with boiling liquid paraffin. Not only was it boiling but actually on fire at the time—so much so that he had to put his hand under the cold tap to put out the flames. Forthwith he dipped his fingers into a solution of plantation rubber latex and came along to see me the next day. The thin coating of rubber appeared to be air-tight and so transparent that one could see quite well the damaged skin underneath. The patient told me that the pain ceased after two hours. As everything seemed very satisfactory I determined not to disturb the dressing until the 12th day, when I found the skin, though tender, completely healed, and the patient proceeded to carry on with his work without further dressings being applied. I have been supplied with a small quantity of latex solution and I propose to try it out further on minor burns.

Cause and Treatment of Stitch

Mr. A. HOLLMAN (medical student, University College Hospital) writes: Having been a victim of "stitch" many times whilst cross-country running, I have been stimulated to inquire into cause and treatment. The writer of the reply to your correspondent's query as to the nature of stitch (see *Journal*, Feb. 10, p. 206) stated that "treatment is practically limited to cessation of exercise." In my experience firm pressure with the hand over the affected area always abolishes the pain; and frequently, but not always, the pain does not recur when the hand is removed. Leaning over to the affected side also helps to relieve the pain. It is interesting how little exercise may be needed to provoke stitch. I have had a sharp attack from walking only 30 yards after a meal. It is not my experience that stitch occurs with greater frequency in cold than in warm weather.

The Teaching Hospitals

"X." writes: Does not the Treasury grant, out of the pockets of the general public, recently announced by the Chancellor of the Exchequer, remind us of the national character of all the voluntary teaching hospitals, both in London and the Provinces. For the breadth of outlook which the national comprehensive service will demand, it will in future be more necessary than ever for the teaching hospitals steadily to continue in the policy of drawing upon graduates of all our universities in a united effort for the health and physical well-being of the British people. Medicine, of all the scientific arts, needs constantly the influence of broad-mindedness and interchange.

Thermometry

Mr. F. R. WALTERS, F.R.C.S. (Farnham) writes: Your contributor (*Journal*, Feb. 10, p. 206) who answered questions about clinical thermometry has not taken into account the atmospheric and other conditions affecting mouth temperatures. In a cool room, or out of doors, misleading readings will follow if the patient opens his mouth for any purpose with the thermometer in it, or shortly before the test; so that repeated inspection of the thermometer is inadvisable in such a place, and where more accurate results are important rectal temperatures are more reliable. Your contributor also writes as if there were a constant difference between rectal, mouth, and axillary temperatures; but this is not the case. In pulmonary tuberculosis, for example, it often happens that rectal temperatures are the same as mouth temperatures in the same patient at the same time; while at other times (perhaps the same day) there may be several degrees of difference. Febrile rises and warnings of complications may be missed if mouth temperatures are relied upon. After exercise, mouth temperatures may be lowered while rectal temperatures are raised. I refrain from giving illustrative cases.

Artificial Respiration and First-aid Instruction

Dr. J. L. BARFORD (Stoke Park, Guildford) writes: As it may be a novelty I venture to mention a very small "tip" which I have employed recently when demonstrating artificial respiration. It simply consists of putting (smuggling, for dramatic effect) a whistle into the casualty's mouth. On expiratory effort the clearness of the airway is made abundantly clear and impresses the students remarkably. It can be employed in Schäfer's, the rocking, or any other method, except, of course, Laborde's! Other instructors might like to copy. Incidentally I note that Dr. F. C. Eve (Jan. 6, p. 21), when describing the successful revival of a drowned child by rocking, states that this was the first (successful) resuscitation by manual rocking. Surely the rocking and swinging employed to induce the newborn infant to breathe, although not strictly a resuscitation, comes under this category? Perhaps I am so old-fashioned that this procedure, which I remember employing successfully, is now superseded.

Hydatidiform Mole

Dr. C. W. F. BURNETT (West Middlesex County Hospital) writes: The answer given under this heading in your issue of Jan. 20 (p. 105) contains no reference to modern theories of aetiology. The most convincing of these—formulated, I believe, by Mr. Barton Gilbert some seven years ago—ascribes the mole formation to the failure of development of embryonic blood vessels in the trophoblast. Food substances passing from the maternal blood through the villous wall by the vital activity of its constituent cells are, therefore, not conveyed to the embryo, which rapidly dies and disappears; the mesoderm of the villus retains the food products, and by a process of osmosis becomes oedematous and cystic. The cytotrophoblast, thriving on the highly nutritious contents of the villus, grows rapidly, assumes invasive characteristics, and secretes increased quantities of chorionic gonadotrophin as your answer describes. The suggestion has been made that this failure of formation of vascular tissue may be one of the results of Rh incompatibility in the parents; however, recent research does not confirm this hypothesis.

Pyretotherapy

Dr. W. F. COOPER (Kingston Hill) writes: Dr. J. R. Edge (Jan. 13, p. 61) suggests that pyretotherapy might be "worthy of a trial." Though the method is used in many cases, no one seems to consider what it is that produces the good effects, or *why* it is suitable in some cases and not in others, except, perhaps, as to antagonism between malaria and spirochaetes. By merely raising the temperature of blood and also of tissues, by whatever means, certain changes must occur; we do not know them all, but do know some of them. For instance, there will be an increase in the number of ions per unit volume, in ionic activity, giving rise to variations in physical effects such as conductivity, *p*H, Eh; and so on. Some of these changes can be brought about by ordinary therapy, and my experience is that they are effective. Information valuable for treatment would result if more attention were given to the effects of raising the temperature. Then one would not consider whether cases were "suitable to" pyretotherapy, but whether pathological conditions would be ameliorated by the effects of it. I consider that cases that are "susceptible" are those due to infection and/or inflammation; but it is not necessary to adopt the higher temperature. This is hinted at in Dr. Edge's letter, but insufficient data are given. A suitable examination of blood should have been helpful; that alone might have made it certain whether his children had an infection or not, and also whether any of the factors produced in pyretotherapy would have been beneficial.

Occupational Cause of Raynaud's Disease

Dr. D. H. MACCORMACK (Manchester) writes: With reference t the answer given under this heading (Jan. 20, p. 106), it is not mad clear whether or not Raynaud's disease and "dead hand" a phases of one and the same condition. This is a point on whic most textbooks still appear to be vague. However, I have personall no doubt that "dead hand" is merely an early stage, and that unles the causative factors are removed, it may, in many cases, develop int Raynaud's disease proper. Incidentally, I believe that "dead hand is listed as an industrial condition in Germany and other countrie and it is difficult to understand why it has so far not found i way into the British schedule.

Romberg's Sign

Dr. E. W. SQUIRE (Reading) writes: Is the answer (Jan. 20, p. 10 relative to Romberg's sign complete? What of the afferent tra through the retina and optic nerve to the visual centre, thence t the cerebellar centre controlling balance? Does not this tract pla an important part in maintaining balance in conjunction with th special sensory nerves? Apropos of this sign I have found it marke in only two cases on the Military Service Boards during the la 5¾ years—i.e., since May, 1939—during which time some thousanc of recruits have passed under my observation.

Translation, Please

Dr. F. DURAN-JORDA, M.D.Barcelona, writes from Manchester I think I can enlighten Dr. Maurice McElligott in regard to th Spanish words for diseases produced by *Bacillus anthracis*. *Bacill anthracis* is known as "carbunco o pustula maligna," and th common name for this is "carbon." In Catalan the scientific tit is "carbuncle" and the common name "carbo." For the staphylc coccal infections equivalent to a boil the word in Spanish "forunculosis," commonly known as "grano." A group of boi together is "antrax." In Catalan the corresponding names a "foruncle" and "antrax," the latter being referred to generally a "vesper," coming from "wasp." As I am not a surgeon myse and have not treated any of these cases there may be more nam in use, but the general scientific terms are as given here.

Dr. H. A. FULLER, M.D.Paris, writes from Glasgow as follows I quite appreciate Dr. McElligott's difficulty (*Journal*, Jan. 13, p. 7 over the words "charbon" and "anthrax" as used in France, an he may find the following helpful. He is quite right in translatin "charbon" as the equivalent of the English word anthrax, an "anthrax" as meaning "carbuncle." Those are the meanings these two words in France to-day; but it was not always s Formerly, in pre-bacteriological days, the word "charbon" (fro Latin *carbo*) was applied not only to malignant pustule but also t boils, carbuncles, and the buboes of plague, in France an apparently, from what he says about Ireland, in other countries a well. Evidently the word was applied to any small *hot* tumo (a burning coal). "Carbuncle" (from *carbunculus*, diminutive *carbo*) was retained in Britain to designate the multiple boil, where in France it is the Greek word anthrax (also meaning coal, course) which was retained for this. Maxwell and collaborato (*Terminologia Medica Polyglotta*; Churchill, London, 1890) give French, anthrax (*bénin*); English, carbuncle; German, Anthra Karbunkel, Brandschwär; Spanish, antrax, avispero (wasps' nest) and for: French, anthrax (*malin*), charbon; pustule maligne English, anthrax (malignant); German, Milzpocke, Milzpustel. Th also give: French, pustule maligne, sang de rate; English, maligna pustule, charbon, splenic fever, woolsorter's disease, maligna anthrax; German, Milzbrand, Karbunkelkrankheit, Brandblatte Spanish, pústula maligna.

Corrigenda

Owing to delay in the receipt of corrected proofs there were thr errors in Dr. M. N. Pai's article "Changes in Personality aft Cerebrospinal Fever" published last week. In the table showi changes in personality after C.S.F. the figure opposite "Fairly good in the second column should be 10; in the last paragraph of t section on headache the word "post-confusional" should be "pos contusional"; the name "Rosenoff" in the bibliography should "Rosanoff."

In his letter on selenium poisoning in the *Journal* of Feb. (p. 276) Mr. A. L. Bacharach meant to write "selenium mig thus interfere with the *in vivo* synthesis of cystine"—not *in vitro*.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY MARCH 17 1945

SHALL WE NATIONALIZE MEDICINE?*

BY

Lord HORDER, G.C.V.O., M.D., F.R.C.P.

When you saw the title of my Address you may have been inclined at first to accuse me of introducing still another word or phrase into our discussions of a subject that interests us all just now, and so of increasing the confusion likely to result already from the use of rather loosely defined terms. This would have been a very poor way of showing my appreciation of the honour you have paid me by inviting me to give this address. I hope to show you that I am really clarifying the position when I speak of nationalizing medicine. By nationalizing medicine I mean doing with medicine what the Socialist desires to do with the land, the banks, the coal mines, and the railways—bring them under the control of the State. This is equivalent to a whole-time State service for all doctors, and that is what I mean by "nationalized medicine."

State Medicine: Confusion in Terms

The term "State medicine" is not free from ambiguity, for we have a State Medical Service already—a service which is certain to extend after the war. "Socialized medicine"—another term that is being used quite often—is more ambiguous still. Socialists use the term "State medicine" and "socialized medicine" as synonymous.[1] They mean by both that the State takes control of the medical profession in all its branches and in all the media through which it operates. But "socialized medicine" may have another connotation: it may mean making medicine more accessible to the people; and, as I believe, this may be done without nationalizing the medical profession.

Then there is confusion as between "socialized medicine" and the new term "social medicine." Since Prof. Ryle occupies the first chair in social medicine, and is its chief apostle, we may accept his definition without demur. Social medicine, he says, is concerned "with the many and varied problems created by sickness in the family and the community as a whole. . . . It embodies the idea of medicine applied to the service of man as *socius*, as fellow or comrade, with a view to a better understanding and more durable assistance of all his main and contributory troubles which are inimical to active health and not merely to removing or alleviating a present pathology. It embodies also the idea of medicine applied in the service of *societas*, or the community of men, with a view to lowering the incidence of preventable disease and raising the general level of human fitness."[1]

Social Medicine not a New Concept

Now, I think I have read all that has been written on the subject of social medicine, and I may say at once that I endorse all the humanist views and aspirations with which this literature abounds. I may be accused of being reactionary, or of trampling upon some people's dreams, if I say that, as here defined, "social medicine" is not a new concept in medicine but is a timely and justifiable challenge, both to medicine and to the State, that they have left undone those things which they ought to have done. But such is my view; for it may be readily conceded that, in searching for the aetiology of disease, medicine has not probed deeply enough into the lives and conditions of the people, so as to bring to light the more ultimate factors that cause unfitness, sub-health, and actual disease. So also it may be readily conceded that in treatment, and especially in preventive treatment, dictated by the discovery of these ultimate factors, medicine has not been nearly as vocal as it might have been. If, for example, overcrowding is a determining factor in the causation of rheumatic fever then it was the business of medicine to discover this fact, to take it into account when dealing with the indications for preventive treatment, and so point out the position to those whose duty it was to take action. On the other side our statesmen, who are at the moment paying so much lip service to what is called "positive" health, have so far done little to ensure for the people the basic conditions that make health possible.

What are these basic conditions? I stated them years ago, and as I cannot state them more explicitly now than I did then, please forgive me for plagiarizing myself. "*First*, enough of the right food; for to preach fitness to the undernourished is sheer hypocrisy. *Second*, shelter, but shelter at a rent which leaves something to buy food with and pay for transport to and from work. *Third*, easy access to the fresh air and the sun. *Fourth*, leisure for play; and—who knows—that may lead to thinking, even the 'high thinking' which the poet lamented is 'no more.' *Fifth*, the amenities, amongst which you will not expect me to omit noise control. And *last*, the giving to every human being a chance *before* he is born and, after death, the decent disposal of his body in the best interest of his fellow-men."[2]

Our Statesmen's Inactivity

What, I say, have our statesmen, who are now so eager to nationalize our profession, been doing about these things? It has taken a major war—a maximum war—to stir them to activity in regard to some of these things. To save our lives—not, mark you, to give us health—good food has been made available at a price that the people could afford; and we have fortunately had a heaven-sent statesman to control this basic necessity. But for how long? Even before the war is over, with other foods in short supply, with a threat that they may remain so for some time yet, with millions in the recently occupied countries half starving, and a few months after we were signatories to the recommendations of the Hot Springs Conference—one of which stresses the importance of maintaining the nutritional level of the people's food[3]—here is the Government reducing the extraction rate of flour, with a consequent sacrifice of essential nutrients which the country was told only four years ago were of great value in preserving the national health! And why is this being done? Why *now*? No convincing answer has yet been given. Our slow start at slum clearance has been greatly accelerated by enemy action—a grim enough commentary, seeing that by this method we have had to sacrifice not only the slum houses but also the folk who lived in them.

There are other obvious things that our statesmen have neglected. To give but one example. In July, 1938, I drew attention to the enormous growth in the quack medicine trade and to the incongruity of exercising no control over the deleterious effect of such trade, and especially of the intimidating nature of the advertisements connected with it, upon the national health at the very time when a serious effort was being made to improve national fitness. The Government apologist was at pains to remind me that "people have the right to make fools of themselves in their own way."[4] And only when, later, and for some obscure fiscal reason, it was thought desirable that the tax on patent medicines should be rescinded, did we get one step forward in amending the law so as to make disclosure of the contents of proprietary medicines compulsory.[5]

---

* The annual address delivered before the Cardiff Medical Society, Feb. 21, 1945.

Now all this, and more like it, comes within the ambit of what is called "social medicine." It is right that the doctor, finding these things to be the answer to much of the problem of the people's unfitness, should say so, and should do his utmost to stir the Government to do something about them. Medicine is, it is true, a social science,[6] and politics is only medicine on a large scale.[6] But it is *not* the doctor's job to *do* these things—which is what emerges logically from much that is preached about "social medicine." Indeed, I feel that the Socialist peeps out rather unmistakably through the thin garb of Prof. Ryle's humanism. His use of the word "comrade" is not, I think, entirely fortuitous. But, speaking for myself, I believe it is paramount that we doctors remain detached from political colour. For the doctor there can be no "left" or "right." For him there is only expert knowledge, a rooted adherence to truth, horse-sense, and, as I have already allowed, a humanist outlook, which, after all, means nothing more nor less than a love for his fellows and a passion to help them, body and soul. He is the good doctor who, guided in his work by the light of science, can also, like Abou Ben Adhem, say quite boldly to the angel: "Write me as one who loves his fellow men."

Freedom of the Profession

Detachment from this business of right and left, then, first. Next, we must continue to merit and to enjoy the public confidence as must, and do, His Majesty's judges, who must be intellectually and spiritually incorruptible in the presentation of *Pax Britannica.* Detachment, public confidence, and, I will add, courage, these are essential, but withal the fundamental note in the doctor's ideal is freedom. But what happens to our freedom if we are part of a nationalized service? Let me be clear; I am not speaking of our freedom as individuals and as citizens: we all accept certain restrictions to our freedom in the public interest: I am speaking of our freedom as members of a profession. We must preserve "free speech on medical matters, free criticism of medical affairs, and free publication of scientific work."[7] If medicine is nationalized it is to a large degree monopolized, it is stereotyped. Most of us believe that if an industry is monopolized a disservice is done to the community: how much greater the disservice if a profession, if medicine, is monopolized? This risk to medicine's freedom must be watched jealously or we may lose it; lose it even when those who steal it from us do so with the best intentions in the world—with good intentions but with mistaken action. I have recently quoted an incident in the life of Herbert Spencer, and I do not apologize for doing it again. Herbert Spencer was speaking to an audience in New York, and he had the courage to utter these words: "One of your early statesmen said, 'The price of liberty is eternal vigilance.' But it is far less against foreign aggression against liberty that this vigilance is required, than against the insidious growth of domestic interference with personal liberty."[8]

There is a growing feeling among thinking folk that "the biggest fight before us in post-war days will be for individuality. It is the kernel of democracy, the biological basis of the struggle for freedom."[9] Someone has said that the best that is in medicine is a by-product of science. If this be true, it is essential that medicine, like science, shall enjoy "tolerance, freedom from restraint, and a recognition of the value of individuality."[9] My reference to the individual leads me to emphasize the fact that he also has his responsibility in the matter of fitness. You can't *make* a man healthy. You can keep the ring for him; you can make available the means of health (the State's job); you can point the way (the doctor's job); but the rest is with him. I refer to this because there is a growing tendency to unload on to the doctor much of the responsibility not only of personal health but of personal morals also. I saw the other day that a distinguished paediatrician spoke of welfare work as being the most neglected branch of medicine.[10] But *is* welfare work really a branch of medicine? I have recently drawn attention to a memorandum just issued by the Medical Women's Federation. It contained a list of matters concerning which the doctor is to help. The list included "the lowering of the standard of honesty and consideration for others; the growing habit of indulgence in alcohol in young people; the loosening of family ties and the toleration of a low standard of reading and of public entertainment."[11] And I wondered if we doctors *really* do society a good turn by carrying not only the baby but the whole family on our shoulders!

The Government's Intentions

But to return to the question of nationalizing our profession. We are told that our fears in regard to the intentions of the Government to nationalize medicine are groundless. In the White Paper there are reassuring words on this subject,[12] and the Minister of Health has repeated this reassurance. He has told us that we are "utterly mistaken" in thinking that the Government's proposals would end in "some sort of State-controlled and regimented service."[13] Well, the fact remains that many of us are left wondering how "general practitioners . . . can escape regimentation and control by the State in a complete service paid out of the public funds and based upon health centres owned by local authorities."[13] We do not accuse Ministers of subtlety: their intentions may be wholly good: but that is the way, we remember, that the road to Hell is paved. Much of the trouble is caused by the ignorance in Whitehall of the essentials of doctoring. How *can* Whitehall know the essentials of doctoring? In its comment on the conclusions reached by the B.M.A. Representative Body the *Times* said: "From an impressive mass of negative resolutions it emerges only that the conference has willed almost all the ends and rejected almost all the means."[14] Waiving the implied cynicism, I, for one, accept the *Times'* comment as apposite and am quite unabashed.

If any should deny that the White Paper envisages the beginning of a whole-time State Medical Service—and, as I say, its public sponsors *do* deny it—I would remind you that not only have the left-wing politicians welcomed the White Paper as a useful compromise, but Mr. Arthur Greenwood said in the House of Commons that he welcomed the White Paper as a great contribution towards the kind of plan which, in the fullness of time, his party would like to see established.[15]

In the brochure issued by the Labour Party, entitled *National Service for Health,* we are told: "In the Labour Party's opinion . . . it is necessary that the medical profession should be organized as a national, full-time, salaried, pensionable service." It adds this significant paragraph: "It may be that *for a while* some doctors will wish to be left out of the State Scheme. . . . The nation should make the service so efficient that no patient could desire a better and every doctor will wish to serve in it."[16]

Again, there was no sort of doubt in Sir William Beveridge's mind as to what would happen to the general practitioner in a very short time if Assumption B of his report were implemented: he would be squeezed out of existence. Said Sir William: "The possible scope of private general practice will be so restricted that it may not appear worth while to preserve it."[17]

The system of State control prevalent in Russia is often held up to us as a model which we might usefully follow; but it is necessary to remember that the slow evolution of our own Health Services, in themselves quite admirable, has been entirely different from anything that has happened in Russia; nor must we forget that "bloody revolution" in that country (a disaster which we have so far escaped here) necessitated a re-start from scratch and (by comparison) a very doctrinaire and detached set of Health Services was documented.

"Free choice of doctor" has become a familiar slogan: but, though not impossible of attainment, this would be almost impracticable if all practitioners were State-controlled. So much so that if medicine were nationalized the "black market" in doctoring would be terrific. What matters quite as much is that the spirit of individual initiative and adventure which has always characterized British medicine would be seriously damped, and men and women with good brains and healthy ambition would no longer be attracted to the profession.

The position of the voluntary hospital, in which, again, initia- ve and individuality have free play, and which has come to ave a unique status in this country, is rendered precarious y the form of control of the hospital services in general as utlined in the scheme now before the public. The voluntary ospital is certainly the medium through which the most triking advances, both in clinical knowledge and in laboratory esearch, have been made. From this type of institution the est-trained exponents of medicine are disseminated. As a eld for education it is essential to progress, and its survival ust be encouraged, not merely permitted, in the national terest.

Steps that should be Taken

I referred earlier to certain basic matters concerned with the ation's health which it was the business of the State to see . There are things more nearly connected with our Health ervices which are crying out to be done and which come roperly within the function of Government action. We learn rom the White Paper that the State proposes to interest itself medicine as applied to the individual citizen.[18] Well, we ave been pressing for this for a good many years. We have rged that in this relation the great help which the State can ive is in improving the machinery rather than in telling us ow we should do our doctoring. I am made a little tired by eading the homilies directed towards us, both in the preliminary aragraphs of the White Paper itself and in the speeches of the oliticians.[19] And not only in the speeches of the politicians. was a prominent Socialist member of our own profession ho, speaking to medical students a short time ago on the ssue of a nationalized Health Service, said: "You will never, hope, be content to be a tradesman in health matters, merely elling your skill in the treatment of declared disease to those ho can afford to pay for it and refusing it to the rest."[20] hades of Hippocrates!

Let me speak of a few of the things from which the citizen ould have derived a great deal of good. Many of us have or a long time stressed two steps which the State should ake, both of which are long overdue—the regionalization nd rationalization) of the hospital services and the inclusion f the dependants of the workers in the National Health nsurance Scheme. Regionalization of the hospitals and the etting up of health centres would provide the best possible asis for the organization of a national consultative service, mbracing physicians, surgeons, pathologists, and "special epartment" men! It becomes clear to-day that both of these ng-delayed steps are doomed to await the birth of the pro- cted nationalized service.

Another and very important part of our health services in eed of State help is the Nursing Service. Beyond taking it or granted that any scheme depends for its success upon an fficient nursing service, the White Paper is almost mute on is vital subject. We have too long paid only lip service the nursing profession. Until the State recognizes its duty relation to the nurse's training and makes it possible, by dequate grants for the purpose, that the student nurse shall e recognized primarily as a useful citizen in training, rather an as merely an employee of the hospital—until this state f the student nurse is recognized and supported, recruitment to the profession from girls with the best brains and the eenest natures will continue to lag and efficient nurses will ontinue to be scarce. This starvation will continue to show self also in the ranks of the District Nursing Service, a branch f the profession upon which the country will certainly rely ore and more in the future.

In whatever ways the State decides to advance in the direction f improving our Health Services it is clear that we shall need any more doctors. The heavy expenses attaching to the ducation of doctors must be shared by the State and in a umber of ways—through much larger university grants, rough subsidies to recognized medical schools, through holarships and bursaries.

Then Research—our millionaires have been most forth- oming, and we are grateful to them. But there must be a uch clearer official recognition of the essential contribution hich research makes to the efficiency and progress of medicine. he degree of recognition which research gets at present is eflected in the fact that the White Paper disposes of it in thirteen lines, most of which are taken up by saying that the present state of medical research is satisfactory and requires nothing further done about it.[21]

Our Case with the State

I have tried to indicate the main ways in which the State can function in society's interest in the field of health. It will have been seen that all these ways really concentrate upon the machinery of medicine and making it possible for the personnel to be efficient. The rest is up to us, up to Medicine. Our case with the State is surely just this: we say in effect, "If you will improve the machine whereby *availability* of medical service to every citizen is made possible, we will work the machine in the manner that we know from experience to yield the best results." But be it noted that we do *not* think (or I should say most of us do not think) that if doctors are made *a part of the machine* the same degree of efficiency will follow. In other words, many of us believe that to nationalize medicine is not only an unnecessary innovation but one which is unlikely to give the best results in medicine in this country. If we find the public uncertain it is our bounden duty to convince it of this.

I believe that the public, when it is really stirred to consider the matter, when it really thinks—for up to now it has been largely complacent, mildly intrigued by what it takes to be a squabble between the doctors and the politicians—will decide against making all doctors Civil Servants. I say, when it really thinks, when it remembers that it is the doctor–patient relation that matters, and that if this be broken up, whether in the name of insurance or social security or some other economic consideration, we shall lose something that is fundamental in our social as well as in our personal life.

Doctor–Patient

There is in Nathaniel Hawthorne's *Scarlet Letter* a description of the ideal doctor–patient relation which I should like to read to you. Speaking of the doctor, he says: "He deemed it essential, it would seem, to know the man before attempting to do him good. Wherever there is a heart and an intellect, the diseases of the physical frame are tinged with the peculiarities of these. In Arthur Dimesdale"—(that is, the patient)—"thought and imagination were so active, and sensibility so intense, that the bodily infirmity would be likely to have its groundwork there. So Roger Chillingworth—the man of skill—the kind and friendly physician—strove to go deep into his patient's bosom, delving among his principles, prying into his recollections, and probing everything with a cautious touch, like a treasure seeker in a dark cavern. Few secrets can escape an investigator, who has opportunity and licence to undertake such a quest, and skill to follow it up. A man burdened with a secret should specially avoid the intimacy of his physician. If the latter possesses native sagacity, and a nameless something more,—let us call it intuition; if he show no intrusive egotism, nor disagreeably prominent characteristic of his own; if he has the power, which must be born with him, to bring his mind into such affinity with his patient's, that this last shall unawares have spoken what he imagines himself only to have thought; if such revelations be received without tumult, and acknowledged not so often by an uttered sympathy as by silence, an inarticulate breath, and here and there a word, to indicate that all is understood; if to these qualifications of a confidant be joined the advantages afforded by his recognized character as a physician;—then, at some inevitable moment, will the soul of the sufferer be dissolved, and flow forth in a dark, but transparent stream, bringing all its mysteries into the daylight."[22]

Assuming this doctor–patient picture to be true—even though, as here described, it is an ideal which, on our side, we too often fail to reach—can we visualize it as being possible of attainment if medicine is nationalized? I don't think we can. I believe that the doctor–patient relation would receive a rude shock from which it would recover only when the individual emerged once more to triumph over the totalitarian mentality that is to-day threatening to enslave even our democratic country.

Conclusion

If, finally, any one of you should ask me, point blank: "Do you see hope in the future of medicine?" I should reply:

"Yes—I see more hope, both for ourselves as doctors and for the people who will come under our care, in the future of medicine than perhaps in any other single thing in the new world towards which we are hacking our way. We at least have not—yet—forfeited the trust of people for whom we work; we at least have not—yet—turned inwards in despair, bartering our spirit of adventure for a mere hope of security. We stand for sane knowledge, selflessness, and mercy in a world gone mad. We cannot let down these people who trust our profession, and it is in this firm resolve that we shall face the future of medicine."

PREGNANCY AND DIABETES

BY

MARY A. M. BIGBY, M.D., M.R.C.O.G.

Obstetrician, Central Middlesex County Hospital

AND

F. AVERY JONES, M.D., M.R.C.P.

Physician in Charge of Dietetic Department, Central Middlesex County Hospital

This paper is the study of 12 pregnancies in diabetic women, and in it the wider use of early surgical induction of labour is advocated to diminish the hazards to the infant.

Before insulin was introduced pregnancy in the diabetic was extremely dangerous for mother and child. According to Whitridge Williams (1909) the maternal mortality rate was 27% during pregnancy, labour, and the puerperium, and a further 23% in the next two years; the foetal mortality rate was 41%. In the early days of insulin treatment Wilder and Parsons (1928), quoted by Skipper (1933), gave maternal mortality as 12% and foetal mortality as 47%. The adequate use of insulin has much decreased the maternal mortality rate, but the foetal death rate remains high. In 1942 Lawrence and Oakley had a maternal mortality of 2% and a foetal death rate of 37%, but when only their 40 completely supervised cases are considered the latter figure falls to 23%. In the most recent American series Bill and Posey (1944) give a 27% foetal death rate.

In this personal series of 12 cases there were no maternal deaths and 2 foetal deaths (17%), one being due to a miscarriage and the other to premature death of the foetus *in utero*.

Maternal Risks

The diabetic risks to the mother are ketosis and hypoglycaemia, particularly in labour and the early puerperium; but with careful management they can be minimized, and they did not cause difficulties in our cases.

Increased liability to toxaemia is said to be the most important risk, and a high incidence is recorded by American writers. Herrick and Tillman (1938) reported toxaemia in 18%, and White and Hunt (1943) found the incidence as high as 42% in 119 pregnancies, and thought it accounted for the high foetal mortality. The latter have treated certain cases with large doses of hormones, giving 150,000 to 300,000 units of oestrin and 10 to 20 mg. of proluton daily, and reduced the foetal death rate from 40% in a control series to 8%.

In this country, however, Lawrence and Oakley (1942) found toxaemia in only 10% of their 54 cases, though a further 15% had albuminuria and oedema without hypertension, but in none of these cases was the baby stillborn. In this series only one patient developed toxaemia, and she went into labour spontaneously at 32 weeks and produced a live baby weighing 5 lb. 4 oz. She then had a post-partum eclamptic fit, but subsequently she and the baby did well. A second case had hypertension from the 22nd week, when she came under observation, the blood pressure being 160/100 to 180/120, but it fell to 120/80 after delivery. She developed slight oedema but no albuminuria.

Foetal Risks

Diabetics tend to produce fat and post-mature infants. Lawrence and Oakley (1942) think they reach maturity at about 37 weeks, and therefore if left to 40 weeks they are really post-mature. The large size—up to 12 lb.—may be due to excessive absorption of sugar or to increased production of growth hormone from the pituitary. The second possibility is favoured, as it does not seem possible to control the size of the baby by controlling the diabetes, for in this series labour was induced before the 37th week in 9 patients and the babies weighed between 6 lb. 6 oz. and 9 lb., with two exceptions; the baby of the toxaemic patient weighed 5 lb. 4 oz. at the 32nd week and the other 5 lb. 6 oz. at the 36th week, so that all but the last were over weight by the usual standards. The heaviest infant was born to the mother whose diabetes seemed well controlled by 130 units of insulin daily.

Premature death of the foetus *in utero* may occur, particularly if pregnancy is allowed to continue to term, and Lawrence and Oakley mention that 7 of the babies of 19 patients who were left to go into labour spontaneously were stillborn. In this series one pregnancy miscarried at the 23rd week, the foetus having been dead 2 to 3 weeks, and one baby died *in utero* at the 33rd week. Foetal death had occurred at the 32nd week in the latter patient's previous pregnancy, and it was planned to induce labour at the 33rd to 34th week, when the child would be large enough to have a good chance of survival. The patient was in hospital awaiting induction, with the diabetes satisfactorily controlled, when the child died. Lawrence and Oakley report a similar case in which Caesarean section was delayed for a few days to clear up scabies, and meanwhile the baby died *in utero*. In neither patient was toxaemia present.

Hydramnios is particularly liable to occur, and was present in 5 of our series. Five, four, and three pints of liquid were withdrawn from 3 patients when the membranes were ruptured, and 2 others had less severe hydramnios. Neonatal death may occur from foetal hypoglycaemia caused by overdevelopment of the pancreas *in utero*. Sugar was given prophylactically in our series, and this complication was fortunately not seen. Foetal abnormalities are said to be more frequent than usual, but none were found in our cases. One patient, however, since becoming a diabetic had lost her first baby after 3 days from congenital heart disease.

Diabetic Management in Pregnancy

The patients were given 220 to 300 g. of carbohydrate in a diet supplying 2,000 to 2,500 calories. It is important to maintain a high carbohydrate intake, for it is known that the renal threshold for sugar excretion is lowered during pregnancy, and large amounts of glucose—e.g., 50 to 150 g.—may be lost in the urine. It follows that insulin requirements must be judged by blood-sugar readings. Insulin requirements tend to rise in the 2nd trimester and especially in the last 3 months, but may occasionally become less, but this was not observed in our patients.

When the patients first came under observation they were given their usual insulin arrangement. As their insulin requirements increased, for preference they were given soluble insulin in the morning and a mixture of zinc protamine and soluble insulin in the evening. A small or medium dose of zinc-protamine-insulin used in this way prevents early morning

TABLE I.—*Obstetrical History*

MOTHER												BABY		
Age	Parity	Past Obstetric History	Complications in Pregnancy	Duration (Weeks)	Onset of Labour (Method)	Liquor Withdrawn	Delay Before Onset	Length of Labour	Method of Delivery	Complications during Labour	Lactation		Sex and Weight	Progress of Child

hyperglycaemia without appreciable risk of insulin reactions. This valuable arrangement of insulin was described by Lawrence and Oakley (1944). In very difficult cases it may be advisable to use a third injection, giving soluble insulin before lunch.

During labour the usual diet was given as long as possible, and then glucose (or lactose) 15 to 20 g. 2-hourly and an extra 30 g. at the onset of the second stage. The muscular effect of labour reduces the insulin requirements and there is real danger of hypoglycaemia; the dosage must then be decreased considerably. If there is heavy ketosis, as in two cases, extra glucose should be given: 15 to 30 g. hourly may be needed.

After delivery less insulin is needed as a rule, and a satisfactory working arrangement is to give half the usual amount on the following day and build up the dose if necessary. In two patients the insulin requirements remained unchanged in the puerperium. Both mothers who lost their babies had a temporary increase in insulin requirements; the other patients had their dosage considerably reduced. The two patients who were not having insulin before pregnancy had their injections stopped without any ill effects after delivery.

Obstetric Management

Premature delivery at 36 to 37 weeks is advisable because of the risk of foetal death *in utero* near term and of mechanical difficulties due to overlarge babies. The methods available are either Caesarean section or surgical induction of labour.

Caesarean section has been widely advocated for three reasons: because of the large babies, to save the child the risks of labour; because a set operation is a known quantity but labour is uncertain in length and severity; and to enable sterilization to be performed if necessary. Even so, some of the babies may die and the risks of operation to the mother are greater than those of spontaneous delivery. In Lawrence and Oakley's series there were 27 Caesarean sections, with 2 stillborn babies and 2 neonatal deaths, and one mother died from pulmonary embolus.

Premature delivery by surgical induction of labour was advocated by Brandstrup and Okkels (1938), and its further trial was recommended by Lawrence and Oakley (1942), who had had satisfactory experience in 3 patients. This method has been used in the present series, which includes tw primigravidae. High rupture of the membranes by Drew Smythe catheter was performed, and pitocin 2.5 units hourl may be given for 6 doses if necessary. The induction wa performed when it was thought the child would weigh abo 6½ lb., and in most cases this was at 36 to 37 weeks c pregnancy. Labour pains started without undue delay in a but two patients. One was a multipara with hypertension, an after 3½ days' waiting, was finally delivered by lower segme Caesarean section. The other patient had a second surgic induction after 5 days and an additional 2 pints of liqu removed—1 pint having been withdrawn the first time—an then labour began soon afterwards. Delivery was spontaneo in all but one patient who needed a forceps delivery for foet distress. Otherwise no diabetic or obstetric difficulties we encountered, and early surgical induction certainly seemed satisfactory alternative to Caesarean section.

Nevertheless operation may be advisable in certain cases there is any doubt about an easy delivery or if there are an additional hazards. A diabetic patient at present under ou care who has developed Rhesus antibodies in her serum an having lost two previous babies by premature death *in utero* wi certainly be delivered by Caesarean section.

Management of the Baby

For the first 24 hours after birth the babies were give glucose—1 teaspoonful in 1/2 oz. of water two-hourly—to tr to prevent hypoglycaemia. This was given three-hourly fo the next day or two, and the infants were breast-fed or give expressed breast milk as soon as possible. Lactation unfo tunately tends to be poor in diabetic patients, and the chil may need to be given artificial feeds. In this series 3 patient fully breast-fed their infants, and in 4 cases attempts at breas feeding had to be given up after 2 to 2½ weeks. There we no neonatal deaths.

Summary

An account is given of the management of pregnancies in diabetic In a series of 12 cases 10 babies left hospital with their mothers— a better result than in previous published series, and justifying th greater use of surgical induction of labour at 36 to 37 weeks instea of routine Caesarean section.

Our thanks are due to Dr. Bullimore, Mr. MacVine, Dr. Silberstein, r. S. L. Simpson, Mr. Stern, and Miss Titcombe, who kindly ferred cases to us, and to the Research Committee of the Middlesex ounty Medical Society, which facilitated the collection of cases. e also wish to acknowledge our thanks to Dr. Sakula for his sistance with the neonatal infants.

ORTALITY IN CHILDHOOD DURING 1920–38

BY

W. J. MARTIN, B.Sc., Ph.D.Lond.

(Of the Medical Research Council's Statistical Staff)
London School of Hygiene and Tropical Medicine

uring the inter-war period considerable success had attended e efforts to reduce mortality, particularly in the first years of fe. It seems of interest to review briefly the trend of childhood ortality during the 20 years of peace, since with the prospects a continued decline in the size of the child population, and e wastage of young adult life due to war, the health and elfare of the child population will become of still greater portance to the nation in the future. The death rates in ngland and Wales during the first 15 years of life, for males d females for four periods covering 1920–38, are given in ble I. Mortality declined at each age throughout that riod; the greatest relative improvement occurred at ages 2 and 2–3, in which the rates had been more than halved. t ages 3–4 the death rate had decreased by over one-third, d there was an improvement of one-quarter in the infant ortality rate. A slight difference occurred in the relative ends of the mortality of boys and girls during this period. e minimum death rate for girls during 1920–4 was at age , but during 1935–8 mortality did not increase until age . There was no corresponding change in the trend of the ys' mortality, and as a consequence the death rate for girls ed 13 and 14 in 1935–8 was below that of the boys, while 1920–4 the boys had a slightly lower rate at these ages an the girls. The mortality at age 5 showed an interesting nd: in the first period the death rate at this age declined a smaller amount than in the preceding or succeeding e. This kink in the curve has become more pronounced, d in the last period the mortality at age 5 showed no improvement on that of age 4. This break at age 5 in the downward rve of mortality may be due to the greatly increased risk infection that confronts children on entering school life, it may be of significance as indicating a hiatus in child-lfare.

Infant Mortality

Before considering childhood mortality by cause of death is convenient to examine the mortality of infants, since the lk of these deaths are attributed to causes peculiar to the first year of life. The great improvement in infant mortality has arisen mainly from the decrease in deaths from infectious and general diseases. The mortality from diseases peculiar to infancy has undergone only a slight improvement. The rates for various causes are shown in Table II.

TABLE II.—*Infant Mortality in England and Wales*

	All Causes	Congenital Malformation; Congenital Debility; Premature Birth; Injury at Birth	Violence	Infectious and General Diseases
1920–4 ..	77·1	33·8	0·95	42·4
1925–9 ..	70·9	32·2	0·99	37·7
1930–4 ..	62·7	32·2	1·16	29·3
1935–8 ..	56·4	30·6	1·12	24·7

The fall in the rates of the second column was due to the decline of mortality from congenital debility from 8.09 in 1920 to 1.76 in 1938. A matter for concern is the steady rise in deaths due to injury at birth—from 1.22 in 1920 to 2.59 in 1938. A similar trend has been shown by the United States of America, where the mortality from injury at birth rose from 3.9 in 1920 to a peak of 5.3 in 1930 and then declined slightly to 4.8 in 1939. It seems rather ironical that, despite the efforts to reduce mortality, the death rates from violence should increase. In terms of rates the difference of 0.17 between the first and last periods is small, but if there had been no increase 410 fewer babies would have been killed during 1935–8.

Although infant mortality has steadily improved since the beginning of the present century, when the rate was 160 per 1,000 births, a considerable improvement can still be effected. This is shown by comparison with the mortality rate in other countries:

Country	Infant Mortality, 1935–9	Country	Infant Mortality, 1935–9
New Zealand	32	Denmark	64
Holland	38	Germany	64
Australia	39	France	66
Norway	40	Canada	67
Sweden	43	Belgium	75
U.S.A.	49	Scotland	76
England and Wales ..	55	Italy	103

The infant mortality rate of New Zealand is only a little more than half that of England and Wales. In the United States infant mortality has declined faster than in this country. The rates for 1920 and 1939 were 86 and 44 in the U.S.A. and 80 and 55 in England and Wales. A similar difference in trend occurred between London and New York. The rates for London fell from 76 in 1920 to 47 in 1939, while those for New York were 85 and 37. In 1939 the rates for each of the five boroughs of New York were below the rate for London. The values were: Manhattan, 45.7; Queens, 36.5; Brooklyn, 34.9; the Bronx, 32.1; and Richmond, 31.0. It is not possible to assess the relative difference of the maternal and child welfare services of the two countries. In the U.S.A., at present, facilities for maternal care for those who cannot pay are provided for only to a very limited extent out of public funds. Probably a part of the greater improvement in that country is due to the success attending the efforts made by ante- and post-natal clinics to increase maternal efficiency. Efforts have also been made to raise the standard of medical care by postgraduate education in paediatrics and obstetrics for practising physicians; and in New York and some other cities minimal standards for maternity services are enforced as public health regulations. With regard to England and Wales, it appears to be doubtful whether full use has been made of existing child welfare clinics. Statistics in a suitable form are not available, but the reports of the local medical officers of health suggest that, although in some areas over 90% of the children born attended a clinic, the total attendance per birth per year was low—of the order of 10. A fair inference is that the majority of mothers failed to take their baby more than once or twice to the clinic. The relative importance of the factors influencing infant mortality has not been established, since most conditions which have a close correlation with infant mortality have also a high degree of association with each other. Within the country there is a considerable negative correlation between infant mortality and economic and environmental conditions, although a comparison of regions reveals anomalies. The infant mortality rates by social class for four contrasting regions are:

Infant Mortality Rates, England and Wales, 1930–2

Social Class	Wales I	North I	East	Remainder of S.E.
I	43·1	37·8	29·9	33·1
II	52·2	50·3	41·7	38·4
III	70·0	71·9	46·7	41·6
IV	73·0	86·8	55·9	46·8
V	77·4	100·6	61·5	54·0

Within each region there is a definite correlation between social class and infant mortality; but the differences between the regions cannot be accounted for by this explanation, since it is impossible that the environmental and economic conditions of Class II of Wales I and North I are below those of Class IV in the remainder of South-East. Geographical position is hardly likely to account for much of the difference, since very low rates have been recorded in northern countries—e.g., the infant mortality during 1935–9 was 40 in Norway and 43 in Sweden.

Specific Causes

The trend of the most important of the specific causes of death for the first and last periods of Table I is shown in Table III. With the exception of violence and diphtheria, all causes show a considerable reduction in mortality at each age during the 20-year period.

TABLE III.—*Death Rates per 100,000: England and Wales*

10–14	1	0·6	4	1	0·2	0·1	11	12	6	2	55	21	1	1	11	7	2	1	7	8

Principal Communicable Diseases.—The death rate for diphtheria for all ages under 15 fell by 29%, owing to the large decrease in mortality among the pre-school population; at school ages the death rate increased slightly during the 20 years. The pre-school child is generally infected by its older brethren of school age, and the decrease in family density due to the declining birth rate is probably a significant factor in this age shift of mortality. In the U.S.A. a great improvement in mortality from diphtheria has been effected since immunization was introduced. During 1920–4 the mortality rates in the U.S.A. for ages 1–4, 5–9, and 10–14 were 86.9, 42.0, and 11.1—approximately at the same level as in England and Wales; by 1935–8 the rates had fallen to 18.6, 5.9, and 1.3. Thus in the last period American school-children had a mortality rate of one-eighth of that of English school-children. The relative smaller decrease at ages 1–4 in the United States was due to concentrating at first on the immunization of children of school age. Success has attended the campaign for immunization in England and Wales, although not yet on the scale achieved in the U.S.A. There were 1,092 deaths at ages 1–15 attributed to diphtheria in England and Wales during 1943, compared with an average of 2,837 during 1935–8.

A considerable improvement has occurred in the mortality from the other common infectious diseases of childhood. The death rate from scarlet fever has fallen to a very low level: only about 6 in every 1,000 deaths at ages under 15 were attributed to this cause in 1935–8. The rate of the decline in mortality from measles was slightly greater at ages 1–2 and 2–3 than at other ages, but the relative importance of this disease has remained unchanged at ages 1–2, when it was the second most important cause of death in both periods. At ages 2–3 measles has been displaced by tuberculosis and diphtheria from the second position, which it held in 1920–4, and, fo males, by violence in 1935–8. Whooping-cough has declined by a similar ratio for both sexes, and the girls suffered proportionately the same disadvantage at the end of the period as at the beginning.

Tuberculosis.—The mortality from tuberculosis fell considerably during the 20 years, and the relative importance of this disease as a cause of death in childhood also fell. The percentage of all deaths assigned to tuberculosis for age groups 0–1, 1–4, 5–9, and 10–14 in 1920–4 was 1.85, 9.4, 15.2, and 25.4, and the corresponding percentages in 1935–8 were 1.06 9.2, 9.0, and 14.6. Tuberculosis of the central nervous system was mainly responsible for the mortality at ages 1–4. In the United States the trend of childhood mortality from tuberculosis is different from that of England and Wales: instead of a continuous decline a minimum occurs at ages 5–9. The rate per 100,000 white children in the U.S.A. during 1920–4 for ages 1–4, 5–9, and 10–14 were 34, 12, and 15; and in 1935–8 they were 11, 4, and 5. The rates in both periods were below those for the corresponding group in England and Wales, and the rate of decline was greater. In the U.S.A. the mortality decreased by two-thirds during the period, which was abou 10% more than the rate of decline in England and Wales.

Respiratory Diseases.—A large proportion of the death occurring in childhood are attributed to pneumonia. In 1935– about one-seventh of all infant deaths—or, excluding th diseases peculiar to infancy, about one-third of the deaths du to infectious and general diseases at ages under 1, and one-sixt of all deaths at ages 1–14—were assigned to this cause. Th mortality from pneumonia in infancy declined by almost one fifth during the period, while at ages over 1 the death rate wa approximately halved. A further reduction in mortality ca be anticipated in view of the recently introduced treatme by chemotherapy, although this treatment gives only a sma proportion of successes at the extremes of life compared wit that obtained at other ages.

During the first two years of life the greatest decrease i mortality among the causes of deaths in Table III was show by bronchitis. The death rate decreased by two-thirds at age 0–1 and by four-fifths at ages 1–2 during the 20 years. Despi the large reduction in infantile mortality the relative positio of bronchitis remained unchanged: it was the third greate cause of death in both periods.

Other Specific Causes.—Although the mortality from influenz is subject to large periodic fluctuations, during the years r viewed there has been an improvement of from one-third one-half in the death rates during childhood. In both perio diarrhoea and enteritis formed the second most importa cause of death during infancy, and accounted for one-tent of all deaths at ages 0–1. The rate of decrease was less in th first year of life than in the later ages; at ages 0–1 it was on half of that at 1–2 and 2–3. The mortality from violen increased during the first year of life during the 20 years, small decline occurred at each age from 1 to 3, and rates chool age were the same in both periods. The relative imortance of violence during childhood increased for boys but ot for girls. Violent deaths at ages 5–9 and 10–14 formed 7.0 and 18.0% of all deaths among boys and 9.5 and 7.2% mong girls.

Conclusion

This short survey shows that since 1920 there has been a arge fall in mortality during childhood, in which practically very cause of death shared, but it is evident that there is oom for considerable improvement. The mortality level of liphtheria and violence showed an unnecessary and persistent vastage of child life. Although the infant mortality rate was ower than that of the highly industrialized countries of Europe, t was higher than in several other countries. This fact and he regional social class mortality of England and Wales suggest hat the pre-war rate for the whole country could be reduced, robably by one-half.

HAEMATOMETRA DUE TO CICATRICIAL TENOSIS OF THE CERVIX AFTER LABOUR

BY

F. SELBY TAIT, M.B., Ch.B., F.R.C.S.

Gynaecological Surgeon, the Birmingham United Hospital

laematometra after a birth injury to the cervix is a rare event. he following is a record of such a case.

Case Report

Obstetric History.—The patient, aged 24, had been married for vo years. During her only pregnancy she attended an antenatal linic in London, but was transferred to an E.M.S. hospital in the ountry before her confinement. The hospital records reveal that ne had a surgical induction for post-maturity when three weeks ast the expected date of confinement. Foetal distress became vident when the os was almost fully dilated. Forceps were applied, ut were not successful in effecting delivery. The head was then erforated and the extraction became relatively simple. She subequently developed parametritis and was not fit for discharge for x weeks. Even then she felt weak and did not recover her previous ood health. The date of the delivery was Sept. 11, 1943.

History of Complaint.—In November, 1943, she had an attack of ain lasting about three days. The pain was like that previously ccompanying her menstrual periods, but there was no loss. She ıys that she reported to a welfare clinic but that nothing abnormal as found. Similar attacks occurred in December, January, and ebruary. She was then "bombed-out" and moved to the Midnds. In March, 1944, after the usual four-weeks interval, she had nother attack, the pain being more severe. She reported to a octor, who gave her tablets to ease the pain, which again subsided fter three days. A month later, on April 15, the pain came on nce more. This time it was worse than ever and was accompanied y vomiting. On April 18 she reported to the casualty department n account of the severity of the pain. She was found to have a nder abdomino-pelvic swelling and was admitted to the gynaecogical wards.

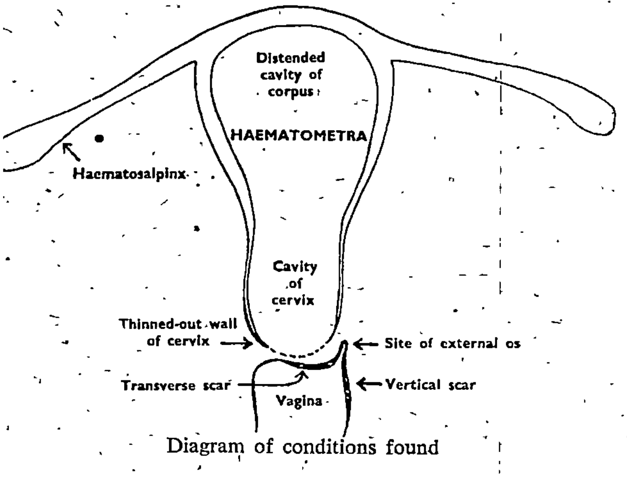

Diagram of conditions found

On admission the history of recurrent pain at intervals of one onth was elicited. On inquiry it was found that her present pain ıs intermittent and was mainly in the lumbar region. When asked it was like labour pains she said that it was, "but much worse." Her general condition was fairly good, though it was evident that the pain was severe. On abdominal examination she was found to have a slightly tender, firm, oval swelling arising from the pelvis and extending almost to the umbilicus, slightly to the left of the middle line. Contractions were watched for, but no alterations in consistence were demonstrable. On examining vaginally no cervix could be found. The abdominal swelling was continuous with a soft bulging of the vault of the vagina. The left vault was drawn upwards and to the left. At its summit was a narrow depression, about a quarter of an inch deep, which would admit the point of a uterine sound. Running into this depression were two scars, each about an inch long; one ran transversely across the vault, the other vertically up the left vaginal wall. Various sizes of probe were used in an attempt to establish communication with the swelling, but without success. The condition is shown diagrammatically in the accompanying figure.

Operation.—On April 18 the abdomen was opened. The free edge of the omentum was found to be lightly adherent to the floor of the vesico-uterine pouch and, more densely, to the left ovary. The body of the uterus was uniformly enlarged to the size of a twelve-weeks pregnancy. The cervix was drawn out to a length of about 4 in., and distended to a diameter of about 1½ in. Each tube had become sealed off at the abdominal ostium and was slightly distended. Hysterectomy was begun, and the uterus, together with the left tube and ovary and the right tube, was separated from its lateral attachments. The cervix was very thin-walled and was distended to the same diameter as the vagina, and it was therefore difficult to identify the line of separation of the two. At this stage the haematometra leaked at its lower end, and several ounces of thin chocolate-coloured fluid escaped. This was mopped away, and for the first time traction was exerted on the uterus. It was then found that the thinned-out anterior wall of the cervix had been completely torn across transversely, and its lower part could not be identified. The posterior attachments of the cervix were next divided and the uterus was removed. The bed of the uterus was inspected, but no sign of any intercommunication with the vagina could be made out, even when a finger was inserted in that organ. After peritonizing the raw area the abdomen was closed.

Convalescence was uneventful. When the patient was examined six weeks after discharge from hospital the condition of the vagina was the same as before operation, except for the absence of the swelling. The depression indicating the position of the cervical canal was still drawn upwards and to the left, and fixed in that position.

Comments

Haematometra is most commonly due to a congenital deformity, and then develops when menstruation begins. Acquired haematometra may be due to a variety of causes, the commonest being neoplasm of the cervix. Carcinoma, fibroadenoma, adenomyosis, or operations for these conditions, have been reported. Herring (1939) has published a case in which haematometra followed radium treatment for benign haemorrhage. Schockaert (1938) records a case due to cervical ulcer in prolapse. Cicatrization following cauterization of the cervix is a recognized cause. Caustics, stem pessaries, and gonorrhoeal and diabetic vaginitis have also been cited.

In a series of 19 cases reported by Bernstein and Walter (1939) congenital causes were responsible for 11. Of the remaining nine cases only two could be ascribed to obstetric injuries, and in each there was a vesico-vaginal fistula. In one the haematometra was found at operation nine years after childbirth; in the other the condition was found three months after delivery, and was due to adhesions in the fornices.

In the present case it seems, from the history, that the operation was performed during the sixth menstruation into the closed uterine cavity. There had been regurgitation of menstrual fluid into the tubes, which at the time of operation were sealed at the abdominal ostia. The adhesions of the omentum to the floor of the vesico-uterine gutter suggest that there had been a spilling into the peritoneal cavity at some stage before the tubes had become sealed off.

Two interesting features are the complete obliteration of communication between the uterus and the vagina, and the distension and thinning of the cervix. It is possible that the cicatrization occurring after the parametritis had drawn the lower end of the cervix upwards and to the left, and that this had been followed by sacculation of the cervix when the menstrual fluid filling this organ had been subjected to pressure by uterine contractions. The remaining part of the cervical canal might then have become subject to a "valve-action," with elongation and lateral compression, causing its virtual obliteration. That some such sacculation was present is evident from the relative positions of the distended cervix and the site of the obliterated os externum.

In most cases of acquired haematometra the stenosis is incomplete and there is some leakage past the obstruction. So complete an obstruction and so extensive a haematometra as that here described must be very rare.

FAILURE OF IMMUNITY RESPONSES IN LOCALIZED DISEASE

BY

W. HOWARD HUGHES, M.D.

(From the E.M.S. Laboratory, King Edward VII Memorial Hospital, London)

During investigations on the influence of inflammation on immunity, evidence accumulated which suggested that, once a condition had become localized, there was a change in the absorption of substances from the site of inflammation and that the zone around the focus acted as a selective membrane stopping entry of substances of high molecular weight into the body. This conception found some support in the literature both from the work on the permeability of the tissues to dyes (Menkin, 1935, 1940) and from the work on staphylococcal lesions by Fleming (1939) in this country and by Hite, Banks, and Dack (1938) in the United States. The former showed that the level of staphylococcal antibodies was not raised above the level for the general population in persons who had suffered from a series of boils, while Hite and his co-workers found that patients with persistent sinuses from osteomyelitis also showed no rise in antistaphylococcal haemolysins. These workers, too, failed to demonstrate any absorption of antigens or of antibodies introduced into these natural sinuses in man or into artificially induced sinuses in animals.

The list of substances already thought not to be absorbed from inflamed areas includes various vital dyes, particularly trypan blue, horse serum, typhoid and paratyphoid vaccines, staphylococci and their toxins, and *B. botulinus* antitoxin. One recent observation supports this general picture. McClean (1943), in the course of work on gas-gangrene infections, found that animals dying from *Cl. welchii* infections had no *welchii* toxin in the circulating blood but large amounts localized in the infected muscles.

It is desirable for three reasons to settle the question whether antigens are absorbed from a chronic focus. First, it is taught that there is no necessity to stimulate the body's specific antibacterial defences during the course of naturally occurring disease, as adequate or even excessive amounts of antigen are already reaching the body from the lesions; secondly, it is possible to show what organism is causing a disease, since during the course of the disease, or in convalescence, the specific antibodies will always appear in the serum; thirdly, the absorption of bacterial products will account for all the toxic effects seen in inflammation.

Infections of the Urinary Tract

In the past difficulty appears to have arisen because the diseases on which the work on specific immunity has been done were all those in which there is a septicaemic phase—for example, lobar pneumonia, typhoid fever, syphilis, bacterial endocarditis, streptococcal septicaemia, and puerperal fever. From these conditions it has been argued by analogy that the less spectacular conditions of localized disease had the same general immunity pattern. One way of demonstrating the incorrectness of this supposition is to examine the serological responses of patients with localized diseases in which the diagnosis is so obvious that the identification of the infecting organism needs no serological support. The first series of cases recorded below had an infection with one single organism in an area which is normally sterile—the urinary tract; they ran a normal course and responded to the normal treatment. The accompanying Table shows 22 such cases. The cases were taken in sequence; only those organisms which auto-agglutinated i saline or which agglutinated to a high titre with all normal ser were excluded. Four strains were discarded for these reason The duration of the infection ranged from one week to man years, the ages of the patients from 22 to 76. In the older ag group, most of whom were men, a partial obstruction wa present in some of the cases. It will be seen that 16 patient show no trace of agglutination of the autogenous organism ; o the remainder only 3 reach a titre of 1/25.

Case	Age	Duration	Agglutination	Organism
1	22	6/12	1/25	Coliform
2	22	2/12	0	"
3	23	3/52	0	"
4	23	2/12	1/25	Proteus
5	23	1/12	0	Coliform
6	24	7/12	1/2	"
7	24	3/12	0	"
8	31	2/12	0	"
9	36	2 years	0	"
10	42	1/52	1/8	"
11	49	6/12	0	"
12	50	3/52	0	"
13	53	Years	0	"
14	53	"	0	"
15	60	"	0	Proteus
16	60	"	0	Coliform
17	61	2 years	0	"
18	62	Years	0	"
19	64	9/12	0	"
20	68	8/12	1/4	"
21	75	Years	1/25	"
22	76	"	0	Pyocyaneus

These results may be compared with those given in cases i which coliforms may reasonably be held to have reached th blood stream.

Case 23.—The patient had an arthritis of one wrist. The cultur from the joint gave a pure growth of coliforms. The patient's seru agglutinated suspensions of the organism to a final titre of 1/212 Complement-fixation tests, using the suspension of the organism a antigen, were positive even with a dilution of the serum to 1/128

Case 24.—The patient, an elderly male, had an old stricture of th urethra, in association with which there had been no fewer than s abscesses as well as persistent cystitis. Cultures of pus from a abscess and of the urine gave the same coliform in pure growt This was agglutinated to 1/640.

Peritonitis

To discover whether the usual cases of peritonitis behave as localized or as generalized diseases from the standpoint o their immunity responses, four patients who had all bee admitted together were examined ; one of these had a perforate gastric ulcer, the others perforated appendices. All ha peritonitis and ran a perfectly normal clinical course aft drainage, leaving hospital in three to four weeks. It wa impossible to distinguish clinically between the cases as to th degree of infection, the severity of the peritonitis, or the effec of the toxaemia on the patient, though the bacterial content the exudates was different in the four cases; the organism isolated were tested against the patient's serum either f agglutination or for complement fixation or precipitins.

Case 25.—Perforated gastric ulcer. Pus sterile.

Case 26.—Perforated appendix; cultures—coliforms. Test on 14 day of illness: agglutination and complement-fixation tests negativ Repeated on 21st day, tests still negative.

Case 27.—Cultures—coliforms and haemolytic enterococci. C 9th day: agglutination of coliforms negative; complement fixati with both organisms negative. On 16th day: agglutination coliforms to 1/16; complement fixation with coliforms to 1/ Complement fixation with enterococci negative.

Case 28.—Perforated appendix. Cultures—*Staph. aureus* and a enterococcus. On 14th day: precipitins and complement-fixing an bodies not found. On 21st day, still negative.

These last three patients were completely recovered fro their infections at the time of their leaving hospital. It might argued that antibodies might have been present later in co valescence, but it is certain that they were not present in tim to influence the local disease.

Diseases of Respiratory and Alimentary Tracts

In attempting to obtain the same type of information localized diseases of the respiratory or alimentary tracts, th problem is complicated by the difficulty of finding cases which only one organism is isolated and in which, in the absence of serum antibodies, there can be definite proof of the identity of the infecting organism. The following cases were chosen as the nature of the causal organism was not in reasonable doubt.

Case 29.—Infection of the lacrimal sac for two years. Cultures gave pneumococcus Type 20 in pure growth. The patient's serum contained no agglutinins or capsule-swelling antibodies against the autogenous strain.

Case 30.—Pleurisy for over a month. Fluid gave a pure culture of pneumococcus Type 4. The serum contained no capsule-swelling antibodies, but agglutinins were present to a titre of 1/4.

Case 31.—Pleurisy following mild pneumonia. Exudate gave a pure culture of pneumococcus Type 1. The serum contained no capsule-swelling antibodies; agglutinins present to a titre of 1/4.

Case 32.—Empyema for four weeks. Exudate gave a pure culture of pneumococcus Type 1. Slight swelling of capsules to a titre of 1/2, agglutination to 1/4, with a trace microscopically to 1/8.

Case 33.—Empyema for 12 days, no history suggesting previous pneumonia. Pure culture of pneumococcus Type 1. No capsule swelling, but agglutination present to 1/8.

Case 34.—Chronic sinusitis. Pus gave almost pure cultures of Pfeiffer's bacillus. Patient's serum gave no sign of agglutination against the autogenous organism. Similar results have been obtained with acute and chronic infections of the nasopharynx with this organism. Patients with *Str. viridans* infections gave no complement fixation against the autogenous organism.

Case 35.—Pleural effusion for about 6 weeks. *B. pyocyaneus* in pure culture obtained from the exudate. Serum showed no agglutinins.

The next group of cases shows the reaction of children who carry the pneumococcus in the nose or throat and who are considered to have infections of the tonsils and adenoids. While these patients will not give pure cultures of a single organism from the nose or throat, those chosen had a high percentage of colonies of one type. It is this group which would be expected to have the so-called subclinical infection that is credited with the growth of their subsequent immunity.

Case No.	Age	Pneumococcus Type	Serum Reaction
36	12	10	Nil
37	5	23	"
38	5	12	"
39	5	6	"
40	5	6	"

The difference between the reaction of patients with localized and those with generalized disease is particularly well shown in pneumococcal infections. The classical lobar pneumonia is well known to give a shower of antibodies at the crisis; even the patient whose disease is prevented from running its course by chemotherapeutic agents will still show some antibody response early in convalescence. The next case illustrates this.

Case 41.—Typical history of the onset of pneumonia; sulphathiazole given within 3 hours of the onset of the disease; temperature reached normal within 15 hours and did not rise again. Cultures of the sputum gave a pure growth of pneumococcus Type 3. Serum tested on the 10th day; swelling of capsules demonstrable and agglutinins present to 1/16.

This response may be compared with that obtained in the following two cases, in which the illness was of much longer duration but limited to the bronchi.

Case 42.—Bronchitis for one month without any sign of actual consolidation. Almost pure growth of pneumococcus Type 14 present in the cultures of sputum. No capsule-swelling antibodies and no agglutinins demonstrable.

Case 43.—Case of carcinoma of lung complicated by oedema of the glottis and severe bronchitis. Sputum gave a pure culture of pneumococcus Type 32. No serum antibodies could be detected.

The infections of the meninges are in a separate category of diseases, since, in general, they must be infected by blood-stream spread or by spread from the nose and throat—processes unlikely to be associated with strict localization. An occasional localized infection may occur after lumbar puncture, as in the next case.

Case 44.—A man was admitted for diathermy of a growth of the bladder; this was done under spinal anaesthesia. Ten days later cerebral signs appeared and the patient was found to have a *B. pyocyaneus* meningitis. He died after an illness lasting four weeks. At the end of the third week from the onset of symptoms his serum was examined for antibodies to the autogenous organisms. Agglutination was present at 1/2, absent at 1/4; complement fixation was negative.

One crucial disease for our purpose would appear to be diphtheria. This is a perfect example of a localized disease with remote effects. It is evident that there is an absorption of diphtheria toxin from the lesion and that the localized disease can give a lasting general immunity to the patient. This immunity is an antitoxic immunity, and as, so far as I know, little attention has been directed to the antibacterial immunity, a comparison of these two aspects of the immunity mechanism is instructive. I have been unable to obtain material from more than two cases in the present conditions, but they are sufficient to suggest the answer to the general question of what it is that determines absorption from a lesion. Agglutination tests are not satisfactory in my hands, even with mitis strains, but complement-fixation tests using the autogenous organism as antigen appear to be a good substitute.

Case 45.—An adult had clinical diphtheria for at least five days before treatment; antitoxin was given. The serum, examined in convalescence at the end of the third and fourth weeks, showed no complement fixation with the autogenous strain of mitis diphtheria.

Case 46.—A medical officer who had had previous diphtheria and whose Schick reaction was negative, performed an emergency tracheotomy and developed a sore throat from which the intermediate type of diphtheria bacillus was grown. There were no toxic symptoms and the throat was clear of organisms when the serum was examined at the end of the third week. Complement-fixation tests were negative, but the serum antitoxin titrated for me by Mr. L. B. Holt was at the high level of 0.1 unit per c.cm.—a level three times that usually taken as giving immunity (Glenny, 1925).

Finally, just as errors arose by assuming that all diseases followed the classical immunity pattern of the blood-stream infections, so it would be a mistake to assume, without investigation, that any individual case of apparently localized disease will have no antibodies. While collecting the present series of cases two apparently well-localized conditions were found with good serum antibody titres. There was nothing definitely to prove that the blood stream had been invaded, nor, of course, to exclude such an event.

Case 47.—Infection of the abdominal wound followed an appendix operation; no peritonitis was noticed at operation. Cultures gave a mixed growth of *Str. faecalis* and coliforms. The serum agglutinated the coliforms to a titre of 1/128, and a complement-fixation test with both organisms was positive, equivalent to one plus.

Case 48.—From an abscess arising in the scar of a mastoid operation performed 14 years previously a sequestrum was removed and the cultures of this gave a pure growth of coliforms. These were agglutinated by the patient's serum to a titre of 1/250.

Conclusion

The failure of localized disease to call out the immunity responses of the body can be most easily explained by postulating some interference with the absorption of specific bacterial proteins and toxins from the focus. This is clearly not absolute, as the case of diphtheria toxin shows. The measurement of diphtheria toxin by Pappenheimer, Lundgren, and Williams (1940) shows that it is a small molecule among proteins, and this points to there being a selective filter functioning in the area of inflammation which will permit the passage of some proteins and not of others. Analyses of exudates and oedema fluids (Harkins, 1942) indicate that the only substances being held back are some of the globulins, but as these appear to be the proteins of chief interest in immunity reactions, their retention is important.

Methods have now been devised for obtaining direct measurements of the porosity of membranes prepared from human fibrin, and the results so far obtained suggest that it may be possible to explain these results in terms of selective filtration. It is hoped soon to publish the full particulars of these methods.

If the observations in this paper are accurate it follows that measures designed to enhance the resistance of the body are indicated in those localized diseases not susceptible to chemotherapy; that previous localized disease will not have immunizing value against reinfection with the same organism; and that serological tests are of little help in identifying the causal organism in a localized infection. It also offers an explanation of why a measure of the antitoxic immunity of the serum may fail to give a true indication of the ability of the body to deal with the bacteria forming that toxin.

Summary

In strictly localized diseases the body does not produce serum antibodies to the infecting organism.

This is illustrated by infections of the urogenital system, peritoneum, pleura, nasal sinuses, respiratory tract, and meninges.

The explanation offered is that fibrin forms a selective membrane excluding some of the protein molecules together with larger particles.

A NEW SALMONELLA TYPE: SALMONELLA CARDIFF

BY

JOAN TAYLOR, M.B., B.Sc.

Salmonella Reference Laboratory, Oxford (Emergency Public Health Laboratory Service)

D. G. ff. EDWARD, M.D.

Emergency Public Health Laboratory, Cardiff

AND

P. R. EDWARDS, Ph.D.

Department of Animal Pathology, Kentucky Agricultural Experiment Station, Lexington, Kentucky, U.S.A.

A new type of *Salmonella* has been isolated from a patient with acute enteritis, the organism containing an H antigen in Phase 2 that has not previously been described. Details of its isolation and characters are therefore given.

Clinical History

The patient, a soldier aged 37, was admitted to hospital on Sept. 7, 1942, with a history of severe diarrhoea and generalized abdominal pain. The onset had been sudden the previous evening. No other men in his unit were affected, although they had shared the same food. Midday dinner that day had included canned pork; the patient admitted to having had a large helping.

On admission he was still complaining of generalized abdominal pain and headache. He was obviously ill and dehydrated. His temperature was 100° F. There were no abnormal physical signs and his spleen was not palpable. The urine was normal. His motions were frequent—seven in six hours; they were fluid, greenish in colour, streaked with blood, and contained many white flakes. During the night following his admission his condition deteriorated; the diarrhoea became worse and vomiting of bile-stained fluid started, so that he was unable to take fluids by mouth. By 6 a.m. on Sept. 8 he was very collapsed, with a rapid thready pulse and subnormal temperature. The collapse was treated with injections of nikethamide and adrenal cortical extract; he was also given 1½ pints of glucose-saline intravenously. His condition began to improve; vomiting ceased, but he continued to have abdominal pain and diarrhoea.

The next day (Sept. 9), although his general condition was slightly improved, the diarrhoea was as severe as before. Therefore a course of chemotherapy with sulphaguanidine was begun. A total of 50 g. of the drug was given over 6 days, starting with 16 g. on each of the first two days. Thereafter the patient's condition gradually improved and the diarrhoea got less, until by Sept. 15 he was having only one motion a day, although it was still soft. He was discharged from hospital on Oct. 1, and was able to return to his unit after a stay of three weeks at a convalescent home.

Investigation

A specimen of faeces passed soon after admission was examined bacteriologically. A non-lactose-fermenting organism was isolated which had the cultural characteristics and biochemical properties of the *Salmonella* group. A similar organism was isolated from the faeces on a number of subsequent occasions, but was not found in a faecal specimen passed shortly before the patient was discharged. Three days after the onset of acute symptoms the patient's serum was tested for agglutinins to *S. typhi* H and O, *S. paratyphi A* H, *S. paratyphi B* H and O, and *Brucella abortus*, using 1/80 as the lowest dilution of serum. No agglutination was noted except for a weak partial reaction at 1/80 with *S. paratyphi B.* A blood count showed the number of white blood cells to be 5,000 per c.mm. The urine showed no abnormalities.

Bacteriology

The non-lactose-fermenting organism isolated from the faeces was shown to be a Gram-negative motile bacillus which produced a shiny round colony 1 mm. in diameter on MacConkey agar. The biochemical reactions were as follows: fermentation of glucose, maltose, mannitol, dulcitol, arabinose, rhamnose, sorbitol, xylose, inositol, and trehalose with the production of acid and gas in 24 hours; no action on lactose, saccharose, salicin, adonitol, raffinose, and inulin. The citrate-utilization test was positive; it produced hydrogen sulphide, but indole was not formed and gelatin not liquefied. When examined serologically the organism was agglutinated by *S. paratyphi C* O antiserum. Absorption of this serum by the organism completely removed the homologous agglutinins. Similarly, *S. paratyphi C* O removed all the homologous O agglutinins from an antiserum prepared against the organism. Therefore the somatic antigenic complex appeared to be VI.VII. On first isolation the organism was firmly in flagellar Phase 2, and was agglutinated to 1/40 by Standards (M.R.C.) Oxford non-specific *Salmonella* H serum (homologous titre 1/640). It was tested with single-factor sera containing agglutinins 2, 3, 5, 6, and 7, but was unaffected by these. An antiserum was prepared, and the following absorption tests were made (see Table):

	S. cardiff Phase 2 Serum						
		Absorbed by					
	Unabsorbed	S. paratyphi B (1,2 . . .)	S. newport (1,2,3 . . .)	S. thompson (1,5 . . .)	S. anatum (1,6 . . .)	S. madelia (1,7 . . .)	S. thompson (1,5 . . .) + S. madelia (1,7 . . .)
S. paratyphi B (1,2 . . .)	2,000	< 100	< 100	< 100	1,500	800	< 100
S. newport (1,2,3 . . .) ..	500	< 100	< 100	< 100	2,000	200	< 100
S. thompson (1,5 . . .) ..	2,000	200	< 100	< 100	1,000	400	< 100
S. anatum (1,6 . . .) ..	2,000	< 100	< 100	< 100	< 100	< 100	< 100
S. madelia (1,7 . . .) ..	5,000	500	200	500	2,000	< 100	< 100
S. cardiff	20,000	8,000	8,000	16,000	16,000	8,000	8,000

It is obvious from the table that the recognized Phase 2 strains failed to absorb the agglutinins from the antiserum prepared against Phase 2 of the organism; therefore the strain must have contained a new antigen. This has been designated 10, the full structure of Phase 2 being 1,10 . . .

Phase 1 of the organism was isolated by the inoculation of culture into semi-solid agar containing serum for *S. paratyphi B*, Phase 2. Phase 1 of *S. cardiff* was isolated without difficulty from the first passage. It was agglutinated to titre by *S. thompson* (k) serum, and completely removed the homologous agglutinins from this serum. *S. thompson* (k) was agglutinated to titre by a serum prepared with Phase 1 of the organism, and gave full reciprocal absorption. Phase 1 was denoted by k.

Summary

A new *Salmonella* type has been isolated from the faeces of a human case of acute enteritis. This organism has the antigenic structure VI.VII: k ←→ 1,10 . . ., and is designated *S. cardiff.*

Our thanks are due to Dr. W. J. D. Fleming for his help in the technical investigation of this organism; to Dr. T. J. Hennelly for permission to use the clinical notes of the patient; and to Dr. J. M. Naftalin for some results of laboratory investigations.

Some 150 doctors of the Royal Navy, British and American Armies, and R.A.F. attended a conference held in a Bengal hospital recently, when the work of the regimental medical officer was discussed. Many speakers saw in the duties of the R.M.O. and his relation to the rest of the Army's medical services a similarity with the position of the G.P. at home in relation to the civilian medical services. Both carried heavy responsibilities, and just as the G.P. was the backbone of the profession at home so the R.M.O. was the backbone of the Army's medical service. For the R.M.O. there was often too little reward. His work was at times monotonous, at times arduous, and nearly always taken for granted. He lacked the stimulus of contact with colleagues and with hospital work, and his patients were soon lost to him. The regimental medical officer, working alone and under conditions of maximum discomfort and often of danger, with no one to fall back on for advice, was the embodiment of the R.A.M.C. motto, *In arduis fidelis.*

Medical Memoranda

Sulphonamides and Tropical Ulcers

In an area in which tropical ulcers are common I have had some success when treating the condition with sulphanilamide. The ulcers include the sloughing and phagedaenic types, and there are the predisposing conditions of malaria and poor nutrition. I shall be glad to hear of the results of the same treatment given in other such areas.

Treatment.—Paint the ulcer with 2½% tincture of iodine, especial care being taken to see that it reaches well under the enveloping edges. Allow it to dry, then cover it with a layer of powder made up of equal parts of sulphanilamide and magnesium sulphate. Repeat treatment daily until cured. No bad after-effects of the drug have been observed. *Under no circumstances* should aqueous antiseptic solutions be used. Watery solutions make the ulcer worse.

CASE RESULTS

Case 1.—A schoolgirl aged 11 with malaria. Growing abnormally rapidly for her age. An ulcer of 6 months' duration on the outer side of the left ankle-joint had been treated with antiseptic solutions and ointments by various doctors. The ulcer got worse, with sloughing and gangrenous tissue round the edges. I treated the case first with equal parts of magnesium sulphate and sugar after cleansing with 90% alcohol. The procedure was very painful and cocaine was needed to allay the pain. This treatment was used for 25 days. The patient improved, but was not cured until sulphanilamide was substituted for the sugar. After 8 days of this treatment the ulcer—2 in. in diameter and 1/2 in. deep—was healed. Eleven months later the patient had a second attack, in the same place, after a knock on the ankle. The ulcer, this time much smaller, was cured in three dressings.

Case 2.—A woman aged 40, poor, badly nourished, and with a history of chronic malaria, had an ulcer 4 in. long, 2 in. at the widest part, and 1 in. deep, on the upper part of the right leg. She was cured in two weeks by the same treatment.

Case 3.—A boy aged 13 developed an ulcer and gangrene of the left arm after comminuted fracture. There was an extensive sloughing and gangrenous area extending 4 in.—almost from the elbow to the wrist. The patient was nearly cured after 2 months' treatment by the same routine.

Many other cases were cured by this method. Microscopically some of them showed fusiform spirochaetes and rod-shaped bacilli, pneumococci, streptococci, and staphylococci.

H. MINA, M.D.

The Persistence of Plasmodium ovale

The life-span of all four species of the malaria parasite outside the endemic area in naturally acquired infections is now fairly well known: the quartan parasite may persist in the human body up to 21 years (Shute, 1944), benign tertian three years, subtertian one year, and *ovale* tertian a few months. Moreover, the methods of treatment of the fever produced by the various species of parasite are more or less firmly established, and it is generally understood that *Plasmodium ovale* is the one species most amenable to quinine therapy. That there may be exceptions to this rule the following case record will show.

CASE RECORD

The patient, the wife of a doctor, was seen in Aug., 1939, after having spent one year in Sierra Leone. She had suffered six attacks of malaria during this period. In an attack in June, 1939, definite quartan parasites were found in her blood, and she was given plasmoquine-compound (plasmoquine and quinine) treatment. This had to be discontinued as she became cyanosed and suffered from severe abdominal pain, which was at first thought to be due to intestinal obstruction, but was ultimately ascribed to plasmoquine poisoning—though it should be stated that she had long been known to be the victim of ulcerative colitis. Another attack of fever followed in July, for which she received adequate quinine and mepacrine treatment for one month. After a period of leave in this country she returned to Sierra Leone, where she had several further attacks of malaria; this time a subtertian infection was definitely diagnosed, for which she was treated. She finally returned to this country in Aug., 1942, and has been here ever since.

There was some further fever in Dec., 1942, and though no parasites were found in her blood after prolonged search, on the clinical findings she was treated with mepacrine and quinine for subtertian infection. She kept more or less well until March 5, 1944, when she developed a rigor, with severe headache, vomiting, pain in the lumbar region, and a temperature of 106° F. Similar attacks occurred at 48-hour intervals. Seen on March 10, she looked pale and ill. There was slight enlargement of the spleen, and examination of her blood revealed a fairly heavy infection of typical half-grown *P. ovale* parasites. She was treated with mepacrine and quinine on the usual routine lines, and has remained well since.

DISCUSSION

It is obvious that this lady must have acquired her *P. ovale* infection in Sierra Leone at least 19 months before the parasites manifested themselves in the peripheral blood, and it is also certain that at least one full course of treatment for the subtertian infection had been given during this period. How is it, then, that the *P. ovale* parasites were not extirpated by this course of treatment at the same time as were the subtertian parasites, especially when *P. ovale* infections are seldom known to relapse in this country as do the other species? Why did mepacrine and quinine cure this attack of *P. ovale* infection when apparently it had no influence in preventing it?

This case would seem to support Shute's (1939) theory that malaria sporozoites may remain dormant for long periods underneath the epidermis, where they are unaffected by antimalarial drugs, awaiting an opportunity of finding their way into the blood stream when a suitable state of the host presents itself; or possibly an exo-erythrocytic cycle in the human host exists similar to that in bird malaria—*P. gallinaceum* (James and Tate, 1938)—but which so far has not been demonstrated in human malaria.

From this case it would seem that, so far from being always a trivial affair, it is now becoming apparent that *P. ovale* may occasionally produce a really serious illness with marked objective symptoms such as vomiting and high pyrexia, or, as we have pointed out in a previous paper (Manson-Bahr and Muggleton, 1937), even manifestations suggestive of appendicitis.

Pneumococcal Meningitis Treated by Penicillin

The following record of two cases of pneumococcal meningitis in which a relapse occurred after treatment with penicillin may prove of interest.

Case 1.—A woman aged 70 was admitted to Addenbrooke's Hospital, Cambridge, on Nov. 16, 1944. She was pale and wandering in mind, and there was some rigidity of the neck. However, the pupils and reflexes were normal and there were no signs of middle-ear disease. Lumbar puncture produced a turbid fluid at a pressure of 140 mm. Sulphathiazole 2 g. was given at once and 1 g. four-hourly until next morning, when pneumococci were reported on culture. The dosage was then increased to 1 g. every hour. Twenty-four hours later the pneumococci were reported to be penicillin-sensitive. Accordingly 10,000 units of penicillin were given intrathecally every six hours and 2,000 units intramuscularly every three hours. Twenty-four hours later but few pneumococci were found on culture. On the sixth day of treatment the cerebrospinal fluid was almost clear and a penicillin concentration of more than 50 units per c.cm. after 36 hours dropped to 10. It would appear that to maintain the necessary concentration frequent injections must be given. The patient completely recovered on Dec. 21, was rational and well, and was normal in pulse and temperature.

Case 2.—This patient was a woman of 28 who was 7 months pregnant and who developed pneumococcal meningitis after a bilateral mastoid operation. She was given 8,400 units of penicillin intrathecally every six hours and 16,800 units intramuscularly every three hours for four days. On the third day the temperature was normal and the cultures sterile. She relapsed, however, after 48 hours, became comatose, and died, despite a second course of penicillin. Necropsy disclosed no infection remaining in the mastoid region, but there was meningitis of the vertex.

The total dosage of penicillin given was: Case 1, 270,000 units intrathecally and 910,000 intramuscularly in six days; Case 2, 134,000 units intrathecally and 537,000 intramuscularly in four days.

Cairns *et al.* state that these cases have a tendency to relapse after doses of 7,000 units for five days. They may do so even after larger doses, as in Case 2.

I should like to thank Dr. J. F. Gaskell and Mr. A. Walford for permission to publish these cases.

DONALD GENGE, M.B., B.CH.
Addenbrooke's Hospital, Cambridge.

Reviews

NEUROLOGY OF EYE, EAR, NOSE, AND THROAT

Neurology of the Eye, Ear, Nose, and Throat. By E. A. Spiegel, M.D., and I. Sommer, M.D. (Pp. 667; illustrated. $7.50.) New York: Grune and Stratton.

This magnificent volume provides a survey of the physiology and pathology of the nervous system in so far as they are connected with the eye, ear, nose, and throat, and such a survey necessarily includes a large part of the central nervous system. It embraces therefore all that the specialists in diseases of these organs may be expected to know, and in fact more than the average specialist is likely to acquire and retain in his mental and educational equipment. In the aural section the first chapter deals with the organ of hearing, and it provokes the reflection that a sense organ which plays so great a part in the normal activities of the individual exercises remarkably little influence on the study of neurology, while knowledge of the physiology of the vestibular system and semicircular canals in relation to the central nervous system has made rapid progress in the last thirty years; yet knowledge of the central connexions of the ocular apparatus is by comparison enormous. Although this is a large book, an excellent proportion between the various sections has been maintained, and a full account of the problems which so often present themselves will be found. Only in the case of the syndromes which are caused by the associated paralyses of the lower cranial nerves is the information scattered and unsatisfactory. The work of Burger in marshalling these syndromes into an orderly system has escaped notice. The illustrations, which depict numerous diagrams, specimens, and microscopical sections of the central nervous system, will be found a mine of information, and within the limits determined by the scope of the subject the authors have produced a complete and reliable textbook of neurology, with an excellent bibliography.

TRICHINOSIS

Trichinosis. By Sylvester E. Gould, M.D., D.Sc. (Pp. 356; illustrated. $5.00.) Springfield and Baltimore: Charles C. Thomas. 1945.

A book which deals fully with a single disease can be a particularly satisfying possession when one is confident that it gives all that is worth knowing on the subject. This confidence may be reposed freely in the work entitled *Trichinosis,* by Sylvester E. Gould of Detroit. It was to be expected that this book would be written in the U.S.A., since the disease is much more familiar there than with us; indeed, post-mortem examinations of muscle in that country have shown that about 10% of the population are infested at some time by *Trichina spiralis,* if only to an extent which can have had only slight clinical effects. The history of the disease and its elucidation is well told, from the original discovery of the parasite by James Paget while a student at St. Bartholomew's. (How many people know that two major discoveries in connexion with this disease were made by students, the second being the observation by Thomas R. Brown at Johns Hopkins that eosinophilia is a constant diagnostic sign?)

The contributions of Virchow and Zenker to the study of trichinosis were among their more important if less familiar achievements, and in the German part of the story there is an arresting anecdote about a sceptical veterinary surgeon who was challenged to eat infested sausage meat and duly developed the disease. A passion for raw pork has been many people's undoing: it can apparently be so strong as even to overcome fear of the disease in those fully aware of the risks they run. Such knowledge was of course lacking in Wolverhampton at the time of the only recent big outbreak of trichinosis in this country, but the habit of spreading the contents of uncooked sausages on bread-and-butter to furnish a tasty lunch for workers was a factor in many of the cases there.

For all information on the pathology, diagnosis, treatment, and prevention of trichinosis Gould's book will be found a complete guide. It is profusely illustrated, agreeably and concisely written, and furnished with an extensive bibliography, arranged chronologically from 1822 to 1943.

TUBERCULOSIS AS A SOCIAL PROBLEM

Social Aspects of Tuberculosis. By S. Roodhouse Gloyne, M.D., D.P.H. (Pp. 148. 8s. 6d.) London: Faber and Faber.

When a distinguished pathologist writes a book with this title, we unconsciously prepare for the shock of discovering that there are aspects of the subject which have escaped observation outside the laboratory but have been noted by a scientist at his bench. But the author has no intention of surprising us. He lectures to nurses, and since nowadays "social" medicine is in the fashion, he wishes to make this published review complete by a feat of overcompensation for the social side of the subject which, we suspect, attracts him least.

The earlier chapters, which deal with aetiology, and that obscure but fascinating relationship between soil and germ, are excellent. Lecturers to audiences even more critical than hospital nurses will find Dr. Gloyne's wise meditations on a lifetime's experience very helpful for hints and for reference. The bovine controversy is ably summarized, the question of age distribution is well handled, and the subject of primitive and Colonial tuberculosis is brought in from its usual sphere of neglect. We are glad to see that the view that sanatorium nursing is probably less dangerous than nursing in wards of chronic tuberculous patients receives Dr. Gloyne's support.

Wherever the author can rely on statistics and generalization he is good. But care work and rehabilitation are not aspects of the tuberculosis problem which can be illuminated from such resources, and this end of the book is unconvincing. Rehabilitation of tuberculous patients, in the full sense contemplated in the near future, is a difficult and still largely experimental art. The time has not come when it can be effectively summarized. Dr. Gloyne's book does not quite satisfy the expectations aroused by its name, but it is a good book, the work of an analytical brain, though as such we doubt whether it will set the student on fire with enthusiasm for tuberculosis as a social problem.

ANATOMY OF FOOD HABITS

The Origin of Food Habits. By H. D. Renner. (Pp. 261. 15s.) London: Faber and Faber. 1944.

Wartime restrictions have naturally heightened the interest in food, both scientifically and nostalgically. In this book Mr. H. D. Renner has probed deeply into the origin of food habits rather discursively and in a style somewhat portentous. Nevertheless he adduces much interesting evidence, and makes shrewd criticisms of some food fads and fallacies. Starting with a review of our knowledge of the special senses, he shows how psychological factors predominate throughout. Thus the appetite tires of strongly pronounced flavours much more quickly than of neutral flavours. Hence the objection to *toujours perdrix,* and the revolt of London apprentices against salmon more than twice a week in what now seem far-off days indeed. On the other hand, the slight flavour of bread and potato does not excite this fatigue, which makes them an admirable interlude between stronger flavours. Foods with the richest flavours do not grow at high temperature or sea level, but in higher altitudes with better exposure to the sun. From Rubner's statistics he shows that calorie requirements in different climates vary much less than is commonly supposed. Thus Britain, standing at the head of the list with close on 3,000 calories, exceeds Italy by only a trifle over 300 calories.

Mr. Renner is specially interesting on the origin of the port-drinking habit; starting as a political threat against French wines, and made practically possible for transport to England by fortifying the wine with brandy, it led to the discovery that maturation could take place in bottles. So the prevailing shape of bottles was altered to enable them to lie in bins, which was only possible when cork bark was introduced for sealing them. He remarks that although salt has long been well known for its preservative properties its real importance to the animal economy went unrealized until the relief of muscular cramps, after profuse sweating, by salted water was discovered. It is interesting to know that with prolonged residence in hot climates the output of salt in both sweat and urine diminishes—an important fact in acclimatization.

These are instances of the varied facts embedded in a good deal of verbiage; yet we doubt whether the author will induce us, on his recommendation, to abandon sandwiches or to gnaw bones.

Notes on Books

Mr. MAURICE H. WHITING's little book *Ophthalmic Nursing,* first published in 1926, has now reached a fourth edition. Brief notes on air-raid injuries and burns of the eye have been added, the section on sulphonamide drugs has been rewritten in the light of further experience, and a note on virus infections has been inserted. These and other additions and minor changes bring the book into line with modern developments. As Sir John Parsons says in his brief introduction, good ophthalmic nurses are rare, and although the art of nursing cannot be learnt from books, good manuals are well-nigh indispensable. This is one of them. The publishers are J. and A. Churchill, and the price 6s. 6d.

The ninth edition of Prof. R. A. FISHER's manual of *Statistical Methods for Research Workers* (Oliver and Boyd: 16s.) contains a new section on the testing of homogeneity of evidence used in estimation. It may be important to determine whether different sources of information fully concur in the estimates to which they lead or whether there is a compromise between sets of data which are significantly discrepant. Prof. Fisher shows how a χ^2 test may be applied. This valuable book will continue to spread knowledge of sound statistical technique.

The best part of the little pamphlet *V.D. Lectures for Nurses,* by REYNOLD H. BOYD, M.B., F.R.C.S.Ed., is the introduction; the description of syphilis and its treatment is good, though one of the Hutchinsonian triad in congenital syphilis—i.e., eighth nerve deafness—is omitted; gonorrhoea is dealt with adequately, but the rarity of gonococcal ophthalmia in adults might have been stressed, and some description given of the side-effects of sulphonamides. Chancroid, granuloma venereum, and lymphogranuloma inguinale are so rare in this country as hardly to deserve mention; their omission would have left space for such matters as a description of dark-ground microscopy, details of tests for albumin and bile in the urine, the nursing of cases of dermatitis and jaundice after arsenotherapy, the staining of films, and a number of other procedures which nurses carry out. This publication should prove helpful to all those who assist clinic medical officers, but some of the language might have been simpler; one is led to doubt whether the average nurse knows what obliterative endarteritis, perivascular infiltration, or intertrigo mean, while "the patient should be kept lying *flat downwards*" seems an awkward way of saying *prone* or *on his face.* The paper and general production are excellent, and perhaps their quality accounts for a comparatively high price (2s.). The pamphlet is published by Heinemann (Medical Books) Ltd.

The manual entitled *Hygiene,* by Prof. J. R. CURRIE, who then held the chair of public health in the University of Glasgow, appeared first in 1938 and had very favourable notice in these columns as a textbook for the use of students of medicine and general practitioners. It gave the essentials of personal, domestic, and industrial hygiene and of the extensive provision made for maintaining and improving the public health. In preparing the second edition Prof. Currie has had collaboration from Dr. A. G. MEARNS, senior lecturer in public health at Glasgow, whose name now appears with his on the title page. It is published in Edinburgh by E. and S. Livingstone at 21s., plus 7d. postage. The authors have widened their prospective audience and address the book not only to students of medicine, medical officers, and practitioners of medicine, but to sanitary inspectors, social workers, and others interested in public health. Appearing at this time it naturally has to do with hygiene as enlarged and quickened both by the war and by the development of social medicine. In an endeavour to keep pace with the march of time most of the text has been recast and much written anew, and post-war planning is touched upon in a postscript. New sections on nutrition and dietaries have been contributed by Dr. D. P. Cuthbertson, and the volume now runs to 432 pages, with a number of new figures, some of them reproduced in colour. As before, the proportion observed is judicious, the arrangement easy of reference, and the presentation interesting.

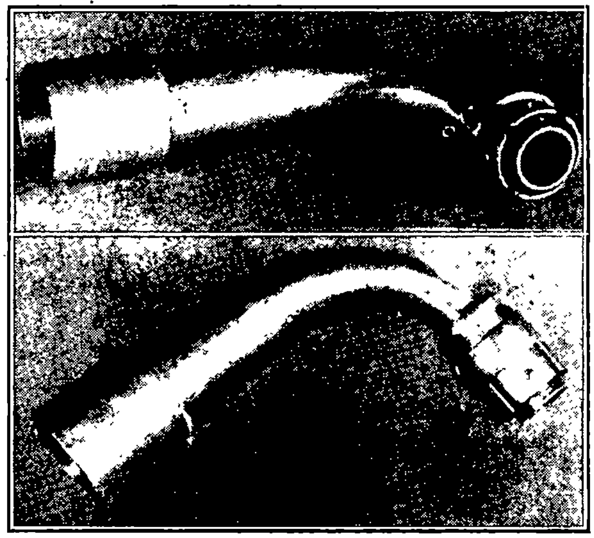
The Czechoslovak Medical Association in Great Britain has shown a truly international spirit in its *1944 Compendium* (Czechoslovak Research Institute, 29, Fursecroft, George Street, London, W.1; 5s.), which is a United Nations issue, ranging over the medical services of many countries. It includes articles on Soviet medical science, the health services of China, the school of medicine in Brussels, medical care in Holland, health in Yugoslavia, medical education in post-war Austria, and the health situation in other liberated or occupied countries. Sir Arthur MacNalty traces briefly the history of public health in England from the pre-Reformation monasteries. The acting director of the Polish Health Services contributes some "Thoughts towards a Better Organization of Health Services after the War," in which he sketches an idea for an international league, a permanent organization of doctors of Allied States, with an international intelligence office to gather and publish all recent scientific achievements and methods, an international body to deal with chemo-pharmaceutical problems, and an international fund for use in an epidemic which might be beyond the resources of a particular country. The compendium is dedicated to Dr. Benes, now on his way back to his country, whom it salutes as the "friend and trustee of the common man."

Preparations and Appliances

A SAFETY ENDOTRACHEAL CONNECTOR

Dr. A. OWEN-FLOOD (London, N.8) writes:

Endotracheal tubes all act more or less efficiently if the rubber is new and retains its elasticity. Any wear or fraying makes for an insecure joint when connexion is made to the source of the anaesthetic, and there is a danger of the tube slipping down into the larynx and thence into the trachea and bronchi. The possibility of this happening is a major nightmare to the anaesthetist, especially if the endotracheal tube is being used as an airway only and the connector is employed to retain it in position. It is here, under the cover of the mask, that an insecure joint may not become evident until it is too late to prevent the excursion of the tube towards the bronchi. Many anaesthetists prefer to discard the connector altogether and rely on the ever-useful safety-pin, borrowed from the nearest probationer, to retain the tube. The numerous pin-holes at the tube's end eventually render it unsafe if the connector is used by another anaesthetist, in the same hospital, who is not addicted to the pin technique.



The device illustrated gives a really reliable joint which is so secure that a degree of force is necessary to pull the endotracheal tube away from the connector. For ease in demonstration and illustration I have chosen a Thornton type of connector, but the device can be applied to most of the leading types now on the market.

The apparatus consists essentially of a split tube or, as it is called in the trade, a split chuck, which is welded on outside the original connector. This outside chuck is split vertically into four broad segments so that the lower ends form four claws. On the inner side of each of these claws is fixed a small stub. A broad ring is fitted outside the chuck, which, when slipped downwards, closes the claws on to the inner tube.

To use the apparatus, the ring is set in the topmost position on the chuck so that the claws will be in the full-open position. After insertion of the endotracheal tube the end is slipped on to the inner tube of the connector and the ring is pushed down, closing the claws, which, with the help of the inner stubs, firmly grip the substance of the rubber tube against the inner connector tube.

May I here record my thanks to Mr. Victor Peck, engineer, for his helpful suggestions and for making the original trial model, and to Mr. Tully and the other directors of the Medical and Industrial Equipment, Ltd., 12, New Cavendish Street, London, W.1, for their valuable guidance and for making the apparatus for me.

BRITISH MEDICAL JOURNAL
LONDON
SATURDAY MARCH 17 1945

THE POLITICAL LOAF

Any last lingering doubts that the European war is drawing to an end have been dispelled by the Government's decision to reduce the extraction of the wheat grain for the National Loaf. And the debate on this in the Lords on Feb. 28 showed remarkably little support for the Government's decision. It may be recalled that in March, 1942, the extraction of wheat was compulsorily raised to 85%, and the primary purpose of this was to save shipping space. At different times the following substances were added to flour: barley, groats and barley, prepared chalk, and dried skimmed milk. Synthetic vitamin B_1, about which there was so much controversy in the early part of the war, was not added to the flour. The motion to which Lord Teviot spoke last month was: "That the standard of 1942—i.e., 85% extraction—should be regarded as a minimum compatible with the maintenance of the health of the people, and that if the extraction rate has been reduced below that standard it shall forthwith be restored." There seems to have been first of all a reduction to 82½%, and then a further reduction to 80%, the first in October last year, and the second in January of this. When the first reduction was effected it was stated that the sacrifice of essential nutrients was "inappreciable." Lord Horder put a pertinent question in the Lords debate when he asked: "How many inappreciables go to an appreciable?" He described the benefits to health which could justifiably be attributed to the consumption of 85% extraction flour during the greater part of the war. "We found," he said, "that some of these cases of ulceration of the stomach healed more and not less quickly under the National wheat-meal bread than they had done under the 75% extraction bread—not, shall I say, a surprising finding, seeing that we know that the healing of ulcers of that type is contributed to by a rise in the general nutrition of the patient." Anaemia had greatly decreased in incidence. His own experience, supported by that of a large number of his colleagues, was that the country as a whole was much less constipated. He reminded the House that increasing the extraction rate from 75% to 80% gave us enough additional bread to provide 1¼ million people with 1 lb. per head a day. In view of the facts that we were one of the signatories to the Hot Springs Conference, and that there was a great shortage of food in liberated countries, the proposed reduction was difficult to understand. Lord Hankey observed later in the debate that the Government was committed to the decision of the Hot Springs Conference to "consider the most effective means of disseminating knowledge of correct feeding among all sections of the population."

It appears that the Government's defence is that new methods of milling worked out at the Ministry of Food's Cereals Research Station at St. Albans had made it possible to reduce the percentage of extraction without "appreciably" lowering the vitamin B content of the resulting flour. The latest results of microdissection of the wheat grain were described by Dr. McCance and Miss Widdowson at the recent meeting of the Nutrition Society, a report of which is published elsewhere in this issue. The typical wheat grain consists of 12.3% of bran, 83% of inner endosperm, 2% of outer endosperm, 1.2% of embryo, and 1.5% of scutellum. The endosperm is rich in carbohydrate, the bran in iron, and the embryo and scutellum in protein and fat. The scutellum is a tiny sheath of powdery matter between the embryo and the endosperm, and contains more than half the vitamin B_1 of the whole grain. Germ, scutellum, and the outer layer of the endosperm are lost with the bran in low-extraction flour; but a flour of 85% extraction can be prepared which contains the germ and scutellum. Only a small amount of vitamin B_1 is, therefore, lost in reduction of extraction from 100% to 85%. But below this the decline is rapid.

Mr. A. L. Bacharach observed that there was a 22% reduction in the available iron when the extraction of wheat was reduced from 85% to 80%. Lord Balfour of Burleigh, who is chairman of the Medical Research Council, quotes a high authority on nutrition thus: "I expect an increase in anaemia to result from the reduction to 80%, and I am confident that if the reduction goes on down to the pre-war 75% or 70% there will be a great increase in anaemia." Miss Copping, at the Nutrition Society meeting, pointed out that riboflavin decreased to about two-thirds of its 1942 value when extraction was changed from 85% to 82½% at the end of 1944. In agriculture the chief need for wheat offals seems to be in the poultry and pig industry, as these animals suffer from vitamin deficiencies unless they are given that part of the wheat grain which popular taste in this country appears to have discarded. But if it comes to the question of pig versus man most people would agree with Viscount Bledisloe that "the children of the nation must in this respect be given a priority over the pigs." In the present state of nutritional knowledge it would seem to be unwise to support a policy of adding vitamins to a low-extraction flour in order to meet the consumer's taste and his apparent vitamin needs. More than one observer has pointed out that there are probably essential nutrients whose existence is yet undiscovered and that we still do not know what we may be excluding from a highly milled flour. There would seem to be much force in the ingenious suggestion made by Dr. Kodicek that high-extraction flour should be used for human consumption and that experiments in artificial enrichment should be tried out in the first place on pigs and poultry.

If we consider vitamin B_1 alone it is well to recall the extent to which this has disappeared from the national diet during the past two or three hundred years. In 1670, for example, the soldier's ration contained 1,000 units of B_1 a day; in 1782 the diet of the parish poor contained between 600 and 850 units; a little over 100 years ago the Poor Law diet of London contained 1,230 units. Just before this war the vitamin B_1 content of the diet ranged from about 290 units at the lowest income level to about 500 units at the two highest income levels.

Those who are better off have a fair chance of making good the deficiencies of wheat-flour by, say, having eggs and bacon every morning for breakfast; the wheat offal is returned to them through the medium of the hen and the pig. The opportunity for doing this is restricted among the poorer classes; and they have almost an addiction to white flour in any shape or form. If, therefore, after the most searching inquiry doctors and experts in nutrition are satisfied that extraction of flour below 85% is injurious to the health of the country, will the country, as represented by Parliament, agree in peacetime to eat a standard National wheat-meal? Or is it more likely to be swayed by such spurious slogans as that in a free country one should eat what one likes? There are fortunately laws which prevent people from eating what they like and drinking what they like, so they may be protected from poisoning, infection, and from consuming undeclared constituents in foodstuffs. Is there in fact any real difference between enforcing laws to prevent people suffering from the water-borne epidemics of the nineteenth century and enforcing a law which is against the consumption of flour seriously deteriorated by the removal of essential nutrients? Unfortunately the large-scale consumption of vitiated flour causes no such dramatic departure from good health as beriberi. It shows itself rather in an insidious lowering of general health, caused by such remediable conditions as anaemia and constipation.

The two obstacles to "bread reform" are public taste and the millers. If the millers were really convinced by sound scientific and medical evidence that white flour was harmful to the health of the people we cannot help thinking that public taste could soon be remoulded if they joined hands with the medical profession and the Ministry of Health in a sustained and widespread propaganda campaign. Some thirty years ago Lord Northcliffe showed what one man and one newspaper could do in popularizing "Standard bread." It would be useless to embark on any campaign to encourage the consumption of whole-meal flour if it is available only in insufficient quantities. Unfortunately it looks as if the Ministry of Food, the Ministry of Health, and the millers have made an uneasy compromise and have lamentably failed to seize this opportunity of restoring to the people of this country its former healthy taste for whole-meal flour.

RELIEF OF OESOPHAGEAL OBSTRUCTION

A few months ago we drew attention in these columns[1] to Prof. Grey Turner's Hume Memorial Lectures on injuries and diseases of the oesophagus, in which he described the possibility of surgical treatment of the otherwise hopeless condition of congenital atresia. That Grey Turner's hopeful views are justified is shown by the published results of Ladd, a pioneer in the surgery of this condition.[2] His paper, which is beautifully illustrated, should be read by those interested in the condition, and especially by paediatricians, obstetricians, and others who have a good opportunity to make an early diagnosis and so refer the patient for surgical treatment. Ladd describes five types of atresia with and without fistulae of various sorts, and discusses the diagnosis and investigation. He makes the point that the use of barium is undesirable because it will cause an aspiration pneumonia if a fistula is present. If a contrast medium is needed a little lipiodol should be used. The simplest way of dealing with the condition is closure of the tracheal fistula and restoration of the oesophagus by end-to-end anastomosis. This is not often possible, but it was done in 6 out of Ladd's 34 operation cases, and 2 of the 6 patients are still living. When direct anastomosis is not possible Ladd recommends a three-stage operation consisting of obliteration of the oesophago-tracheal fistula, gastrostomy, and then oesophagostomy; out of 28 patients 9 are living. Continuity between oesophagostomy and gastrostomy is restored by anterior oesophagoplasty. Of the total 11 living patients the oldest is over 4 years old, and her photograph seems fully to justify the comment that she is a fairly normal child for her age.

The problem of surgical reconstruction of the oesophagus in another obstructive condition—namely, cicatricial contracture—is dealt with in an invaluable article by the famous Moscow surgeon, Serge Yudin.[3] His paper deals with 80 cases, but an editorial footnote brings the final total up to 92, the last 4 patients having been operated upon before the members of the Anglo-American Surgical Mission. Out of his vast experience Yudin discusses the evolution of the surgical technique of anterior oesophagoplasty and in particular the final method he now favours. The whole is illustrated by a most comprehensive series of diagrams, skiagrams, and photographs. Yudin prefers a two-stage operation, excluding gastrostomy. At the first stage a long jejunal tube is freed, great care being taken to maintain the blood supply by preserving the vascular arcades. The bowel is divided and an end-to-side anastomosis made between the proximal end of the intestine and the distal end of the mobilized segment. A long subcutaneous tunnel is now made with either a long forceps or a special tunnelling instrument designed by Yudin himself, and the jejunal tube is carried up into the left side of the neck as high as the mastoid process and so that it lies alongside the pharynx and cervical oesophagus. At the second stage a direct anastomosis is made between the jejunum and the cervical oesophagus. When it has not been possible to draw the intestine up to the level of the pharynx, or if partial necrosis has occurred, the upper portion of the artificial oesophagus must be constructed of skin; Yudin discusses and illustrates the steps of this procedure also. There can be no question that he has made a pre-eminent place for himself in devising this anterior reconstruction of the oesophagus. Out of 88 completed cases the direct operative mortality was only 2; in 21 a total intestinal oesophagoplasty was done.

Anterior oesophagoplasty, however, may not appeal to all, especially if it means numerous plastic operations for construction of an intervening skin tube. Grey Turner[4] described a remarkable case in which he succeeded in restoring normal swallowing by teaching the patient self-dilatation with bougies after anterior oesophagoplasty had

failed and all food had been taken by gastrostomy for 19 years. Self-dilatation is, however, limited in its applicability, especially if the patient is unsuitable, and means of restoring continuity by resection and internal methods of anastomosis must be considered. As yet no final pronouncement can be made on this subject, but the success attending resection and anastomosis for carcinoma of the oesophagus justifies the attempts that are now being made to apply the same methods to cases of simple obstruction. When the lower third of the oesophagus is affected there should be no difficulty in bringing the fundus of the stomach through the diaphragm and, after resection of the diseased segment, performing an end-to-side anastomosis between stomach and oesophagus. Since Adams and Phemister's report of their successful case of cancer treated in this way in 1938 a large number have been successfully operated on, and many cases are recorded in the literature. The problem is less fully worked out for cancer or stricture at the higher, and indeed common, level of the arch of the aorta. Torek's operation of excision followed by gastrostomy and cervical oesophagostomy is rendered more acceptable in the light of Yudin's work, but in spite of this brilliant contribution anterior oesophagoplasty still remains a difficult and distasteful procedure and may bring much misery to the patient and anxiety and disappointment to the surgeon. There can be little doubt that immediate restoration of continuity is the ideal, and that this can be achieved is shown by recorded cases of others. Thus Brock[5] describes and depicts resection of a growth at the level of the bifurcation of the trachea in two patients; the anastomosis lay above the level of the aortic arch and was rendered possible by freeing the upper part of the oesophagus and displacing it to the left or lateral side of the aorta. One patient left hospital eating a normal diet 3 weeks after operation. Garlock[6] also describes a similar procedure which he has carried out on 2 patients, and there seems little doubt that this may become the method of choice in mid-oesophageal growths and will also be applicable to simple stricture. Garlock in another paper[7] analyses his experiences with malignant oesophageal obstruction during the last 8 years. In all, 91 patients have been explored, and in 60 the growth was operable. Twenty-nine patients died, a mortality of 45%. Seventeen are still alive—one 8 years, one 5 years, and one 4 years after operation. The advances in the surgery of oesophageal obstruction, especially that due to cancer, have been great during the last decade, and equally great advances are to be expected during the next few years.

LORD DAWSON

Lord Dawson of Penn died in the early hours of March 7, and the profession mourns his passing. The world at large thought of him as a "royal doctor," physician to four Kings of England, but to medical men and women he was more than that: he was our senior statesman, admired for his courage and wisdom, and loved for his kindness and charming approachability. Young and old of every degree gave him their confidence. Bertrand Dawson had no flying start in life: he carved out his early career by hard work and determination. Good fortune came his way but could not spoil him. If he made few contributions of his own to the science of medicine he had an abiding interest in medical progress and its practical application. This thirst for knowledge from every source, joined with clinical acumen, shrewd judgment, and exquisite tact, earned him fame as a consultant. Other qualities which he possessed—a high sense of public duty and the gift of speech—were seeking an outlet at the end of the last war, when he rose to the front rank in medical affairs. Thenceforward he stood out as a leader, holding fast to all the traditions he thought good and worthy to be preserved, but conscious of a changing world and of the need to look ahead and around. He was the first medical man in active practice to be created a Peer, and he soon made his mark in the House of Lords when matters affecting the health of the people came up for debate.

Sympathetic with the forward movement in medical practice and organization, well aware of the needs and aspirations of our profession, Lord Dawson believed in the British Medical Association and acted up to his belief. His long Presidency of the Royal College of Physicians of London gave him the power to instil fresh life into that ancient corporation. As a member of Council of the B.M.A. he had been diligent in attendance and constructive in outlook, and when the Centenary approached it was inevitable that he should be chosen as President of the Association: in the celebrations of 1932 he did wonders as the central figure. That eventful year was not the end of his interest in the work of the Association, nor (as it turned out) of his willingness to hold office again if asked to do so. Lord Dawson served as an ordinary member of the Medical Planning Commission without reminders of his disappointment at the pigeon-holing by the Government of the report which his Consultative Council put out in 1920. Then in 1943, and again last year, the British Medical Association called him once more to its Presidential Chair. He accepted the unique honour as a duty to his fellow-members, and in that spirit declined no request from headquarters when his influence or help was sought. Even in the last few months, after a severe operation, he kept in touch with the course of events.

ORGANIZATION OF RESEARCH IN INDIA

Prof. A. V. Hill, M.P., paid a visit to India last winter at the invitation of the Government there to discuss and advise on Indian scientific research problems. This is the first occasion in the history of the connexion of the two countries that a distinguished British scientist has been asked to offer such counsel, and it is a happy circumstance that the scientist chosen should be a man of such vision and of such practical grasp of research in many fields as the secretary of the Royal Society. His visit has evidently made him feel strongly that the structure of scientific activity in India needs reinforcement in many respects, and he has produced a report which makes some carefully thought out recommendations. He considers that an Indian Scientific Office should be set up in London, with specialists in various subjects, including medicine, that representative Indian scientists should be attached to the British Commonwealth Scientific Office in Washington, and that young Indian teachers and research workers should be given facilities for advanced study abroad, especially in Britain. He lays it down that in the medical colleges it is essential to have full-time teachers and research workers in all subjects, and he urges the establishment in Delhi of an All-India medical centre where selected students could be trained and receive financial aid in the form of scholarships. Such a centre must be free from all racial, religious, political, or provincial bias; its purpose would be to provide the best type of teacher and research worker, and thereby to foster throughout India a high standard of medical practice. A special hospital for the clinical study of malaria and the bringing of existing research institutes into closer touch with the medical colleges are other recommendations. To facilitate scientific research in general Prof. Hill wants to see a central organization under a Minister without Departmental duties, this organization to have six boards charged respectively with research in medicine, agriculture, industry, natural resources, engineering, and defence. The director and principal administrative officer of each board should be *ex officio* a member of the other five, so that the closest liaison would be maintained. A research grants committee and a studentships committee would serve all six boards. Other points in Prof. Hill's programme are the construction of an Indian central register for scientific and technical personnel, the institution of a central scientific academy—the Indian equivalent of the Royal Society—and help from the Government of India to specialist scientific societies in such a way as would not lessen their independence. He points out, finally, that scientific research in universities is the basis of progress in science. A national policy of grants to universities is necessary, and medicine and biology are two of the subjects which badly need fortification by this means. At the same time he is aware of the drawbacks of making research an entirely Government-subsidized affair, and of the need for enlisting private benevolence in the endowment of scholarships and fellowships and the various means whereby research is assisted.

CAVE CANEM

Pulmonary hydatid disease is usually considered a rarity in this country, although in certain districts it is common enough to be of some importance. Barrett and Thomas,[1] in a remarkable analysis of 19 cases, show that the very infrequency of the disease often causes delay in diagnosis. Although the majority of patients consult a doctor shortly after the onset of symptoms, hydatid disease is usually the last condition to be suspected, and in this way valuable time is often lost. The dog is the source of the trouble, and the town-dweller's dog is as liable to infestation with *Taenia echinococcus* as the countryman's. Ova acquired from the dog are ingested and liberate hexacanth embryos in the stomach which are carried by the portal circulation to the liver, where the majority lodge; but a few find their way to the lungs and other tissues. When a hydatid cyst develops in the lungs it compresses the parenchyma and produces areas of collapse, tension emphysema, pneumonia, and infarction. Cysts near the hilum often rupture into a large bronchus and are expectorated; others erode a vessel, with fatal results, or leak slowly into a bronchus and become infected. Cysts in the middle of a lobe often attain a large size before causing symptoms; mass radiography will probably reveal a number of these "silent" cysts. A peripheral hydatid cyst quickly encroaches on the visceral pleura, and causes pain and erosion of the ribs by pressure on the chest wall. It may lead to a pleural effusion or tension pneumothorax; less frequently the cyst is extruded into the pleural cavity and continues to grow there. Multiple pulmonary hydatid cysts are not uncommon. In rare cases the parasite dies and the cyst degenerates into a mass of brown debris enclosed in the calcified adventitia. More often it ruptures into a bronchus, and the patient may expectorate salty fluid and sometimes the membranes. If these are discharged completely the cyst may heal, and it has been stated that 70 to 80% of hilar cysts resolve in this way. If the fistula is small the cyst usually becomes infected and resembles a lung abscess. Daughter cysts rarely develop in a pulmonary hydatid, and the expectoration of "grape skins" usually means that a cyst in the liver has ruptured into the lung.

Significant diagnostic features include the complaint of repeated small haemoptyses, signs of anaphylaxis, thoracic pain, and the expectoration of salty fluid. Both the Casoni reaction and the complement-fixation test can be valuable in expert hands, but interpretation of them requires considerable experience. Contrary to the accepted description, a hydatid cyst of the lung often has a dented and blurred outline in the *x*-ray film. A diagnostic feature is the presence of a thin crescent of air in the upper part of the cyst between the adventitia and the laminated membrane. Diagnostic aspiration of a pulmonary cyst is a most dangerous operation: it may be followed by rupture of the cyst, severe anaphylaxis, or the production of secondary cysts by implantation.

Although some hydatid cysts resolve spontaneously, Barrett and Thomas consider that the treatment should be surgical. Even spontaneous rupture may be fatal, and the patient with a pulmonary hydatid is threatened by a host of severe complications. If the cyst is accessible from the chest wall it should be opened and packed like a lung abscess, steps having first been taken to ensure that the pleural membranes are adherent at the site of operation. In other cases—for instance, when the cyst is central, when the diagnosis is in doubt, or when irreversible septic changes are present—lobectomy may be the treatment of choice.

Barrett and Thomas have not merely given an authoritative account of every aspect of pulmonary hydatid disease: they have shown that this condition should always be remembered by the clinician when he is considering an obscure opacity in a skiagram of the chest. Their work also serves to emphasize the need for skilled chest surgery in the treatment of this complaint.

A PROFESSION FULLY GROWN

The Dental Board, which was established by the Act of 1921 to share with the General Medical Council the administration of the Dentists Acts, was described by its former chairman, Sir Francis Dyke Acland, as a halfway house. Probably he foresaw the time when it would outgrow its temporary status as a Board and become a Council like that of the medical and other professions. Up to now whatever the Board has done has been under the supervision of the General Medical Council, its preceptor and host. Dentists have had a separate *Register* since 1878, but they have never had complete control over admission to it. In its disciplinary work the Board may only recommend erasure: it is the Council which pronounces it. The G.M.C., moreover, has been responsible, with the co-option of additional members appointed from the Board, for the courses of study and examinations for dental graduates and licentiates. The Board has now come of age, not merely in years but in experience, and the time is approaching when there may be a General Dental Council, with full control of its *Register* and of professional discipline. Reference was made to this possible development at the last session of the Board by its new chairman, Dr. E. Wilfred Fish, who pointed out that during the eventful years since the last Dentists Acts the art of dentistry has evolved into a profession, has acquired a scientific background, and has found a place in the national life which will grow in importance with the passage of time. In its evidence to the Teviot Committee the Board recommended the transfer to itself of certain dental functions from the General Medical Council, and Sir Herbert Lightfoot Eason, the president, has stated that the Council has put forward the same proposal. If these recommendations come into effect the dental profession will be charged with the responsibility for its own management. This must not be looked upon as a divorce from medicine: rather is it the departure of a daughter from her father's house to make a home of her own. In Dr. Fish's words, "just as the child cannot always remain in the home or at school if it is to contribute its full share to the store of human knowledge and play its part in the greater life of the nation, so, we believe, our profession must now take its place by the side of medicine, but no longer under its wing." The association of dentistry with the scientific life of medical schools will be even closer, for the proposal is that in addition to the appointment to the new Dental Council of a representative from each dental licensing body, there will be included six members from the General Medical Council, which members will invariably serve on any statutory committee on dental education and examination which the new Council may set up. The Dental Board since its foundation has done its work well. It found a divided profession and has helped to give it cohesion. It found a lack of university facilities, and has made it financially possible for the universities to establish chairs in dental surgery. It has helped the struggling student with scholarships and bursaries. It has undertaken some novel enterprises for the dental health education of the public. Its disciplinary procedure has been carefully modelled on the lines of that of the G.M.C., and only in one instance to our recollection has its recommendation not been accepted by the overriding body. Such is now the experience of the Board that it feels capable, under a new title and with an enlarged composition, of assuming full control of its *Register* and of professional discipline.

ARTERIAL INJURIES

The Memoranda of the War Wounds Committee of the Medical Research Council have been of outstanding excellence and a very present help in these times of trouble. The latest publication—on the early diagnosis and treatment of arterial injuries[1]—has been prepared by a subcommittee under the chairmanship of Sir Thomas Lewis, whose clinical researches on the peripheral circulation have provided the explanation for many of the phenomena recorded and the basis for much of the treatment recommended in the memorandum. Mr. B. C. Maybury, bringing the fruits of extensive experience of arterial wounds in the war of 1914–18, and the benefits of an early training in the Makins tradition; Prof. J. R. Learmonth, with his special interest in the technique of vascular surgery, in arteriography, and in the methods of research; and Mr. Sol. M. Cohen,[4] with his knowledge of arterial spasm and the care of the ischaemic limb, must all have contributed largely to a monograph which is a masterly review of the subject. It has been written chiefly for the guidance of young medical officers who have had little or no previous experience of the early treatment of arterial wounds. The late effects, such as arteriovenous fistula, are not included. The monograph begins with an account of the morbid anatomy of partial and complete division, and contusion of an artery, arterial spasm, and the factors influencing the development of collateral circulation: stress is laid upon the importance of muscular branches in this process, and consequently upon the serious nature of a wound in which much muscle, as well as the main vessel, is damaged. Spasm of arteries after contusion or a "near miss," and the relation of vascular spasm to traumatic shock, provide one of the most difficult problems. The clinical manifestations of complete division, thrombosis, or spasm of a main artery, which include colour changes in the limb, blistering, change of temperature, oedema (explaining "wet" and "dry" gangrene), pain, interference with the function of motor and sensory nerves, loss of pulse in distal vessels, and the appearance of abnormal pulsating collateral vessels, are described in detail. Then follows a description of the complications of complete arterial block—the greatly increased risk of anaerobic infection, the appearance of Volkmann's contracture or colliquative necrosis with subsequent calcification of muscle, and the rare occurrence of causalgia as a possible result of the ischaemic state. A note of warning is sounded against early muscle biopsy to diagnose the Volkmann state. Partial division of a main artery is indicated by undue bleeding and local swelling relative to the size of the wound, for haemorrhage cannot be arrested by the natural process of retraction of the vessel wall unless the division is complete. If a false aneurysm forms the distal pulse is usually present, but the most constant sign is a short systolic murmur; this shows the importance of listening to all punctured wounds, however small, close to main arteries.

The memorandum must be consulted for the treatment of the several types of injury: it depends primarily on the facilities at hand for operative surgery, and upon the extent of the damage. Descriptions are given of axial anastomosis, which is rarely practicable; of the use of artificial tubes, which, if heparin is also available, may prove to be more useful than they were in 1914–18; and ligation of the proximal and distal ends of the severed artery with simultaneous ligation of the companion vein. In the management of the ischaemic limb full directions are given for the reduction of the metabolic needs of the affected tissues—the assistance of collateral circulation by passive movement and posture of the limb, timely incision for the relief of tension, and the promotion of vasodilatation either reflexly or by sympathetic denervation. Appendices describe the technique of arterial suture, of the administration of heparin, and of sympathetic block. A guide to the writing of case notes in base hospitals and vascular injury centres completes a booklet which packs much information and advice into a small space.

A memorial service for Viscount Dawson of Penn will be held in Westminster Abbey on Tuesday next, March 20, at 12.30 p.m. Admission to the Abbey will be by ticket. Applications for tickets should be sent forthwith to the Secretary of the British Medical Association, B.M.A. House, Tavistock Square, London, W.C.1.

It is now announced that the Canadian Medical Association will hold its 76th Annual Meeting in the Mount Royal Hotel, Montreal, on June 11–15.

---

[1] *Arterial Injuries: Early Diagnosis and Treatment.* By the Vascular Injuries Subcommittee of the M.R.C. War Wounds Committee. M.R.C. War Memorandum No. 13. 1944. H.M.S.O. (4d.)

WHAT IS MARRIAGE GUIDANCE?

The following note has been written for the information of our readers by the Secretary of the Marriage Guidance Council.

In recent years it has been increasingly realized that a vast amount of personal unfulfilment and social disruption can be traced back to marital disharmony. If the stability of the community is largely determined by the soundness of its family life, it is equally true that the stability of the family is largely determined by the soundness of the basic relationship between husband and wife. To increase the number of successful marriages would therefore go far towards diminishing the incidence of many of the social and personal ills which beset us.

This is the *credo* of the Marriage Guidance Council. First formed in 1938, it was reconstituted in 1942 under the joint presidency of Lord Horder and the now Archbishop of Canterbury. A voluntary organization, it welcomes as members all who approve its aims and principles, as set out in its Memorandum.

The Council seeks to foster healthy family life in two ways: by the preparation of young people for marriage and parenthood, and by offering guidance to those in marital difficulties. The first task is mainly educational, the second falls within the general field of social service. In the achievement of both, however, the specialized knowledge and skill of the medical profession must play a vital part.

Preparation for marriage ought properly to include the education of the young in matters of sexual hygiene, the guidance of the adolescent towards a sound approach to mate selection, and the specific preparation of engaged couples for the marital adjustments which await them. It also covers, in its wider compass, the teaching of domestic science and parentcraft. Each of these tasks requires the counsel, if not the active participation, of the doctor.

It is with the preparation of individual couples that this Council is particularly concerned. It is our practice strongly to recommend a pre-marital medical examination for both partners. This should ideally cover questions of general physical and mental health, sexual competence, eugenic fitness, and freedom from venereal disease. In some cases the couples may also desire advice about family spacing and an investigation of their potential fertility. This is not the whole of marriage preparation, for marriage is much more than a physical relationship. But our experience suggests that the doctor's contribution to this work is of immense importance. It is to be hoped that practitioners will concentrate increasingly upon this important aspect of preventive medicine.

Secondly, the Council seeks to offer help in the difficulties of married people. In London we have now had a Marriage Guidance Centre in operation for two years. Experience of nearly a thousand cases has taught us much concerning the scope and nature of this work. It has become clear that an adequate service in this field calls for the co-operation of a team including the doctor and medical psychologist, the parson, the lawyer, the social worker, and others. No one person could deal competently (even if he or she had the time) with the wide diversity of problems which have confronted us. Increasingly we have realized that the Centre must work on a short contact basis, advising in a general way and referring to the private practitioner, the hospital, or clinic where treatment is required. Thus at the Centre itself no treatment, in the technical sense, is undertaken; for that reason the word "clinic" is avoided. The object is to provide a clearing station through which those in need of help can be directed to the proper quarter. Where this means a doctor (as it often does), the latter will handle the case in accordance with the principles of ordinary medical practice, making a brief report to the Centre for record and statistical research purposes. Similar procedure is adopted where a case is handed over to the lawyer or the professional social worker.

Our experience, therefore, confirms that already gained in America over a period of some years, that marriage guidance is a new type of social and personal service in which the co-operation and help of the medical profession are absolutely essential. At present the Council's activities are increasing rapidly up and down the country. We would be very glad to know of medical men and women who are already specializing in this work, and who would be willing to co-operate with us in furthering its development in their own localities. Inquiries should be addressed to the Secretary at 78, Duke Street, London, W.1.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

Though the work of the London School of Hygiene and Tropical Medicine has been sadly frustrated by the war and much clinical teaching and research has been brought to an end, the latest report of the acting dean, Prof. Major Greenwood, shows that not a little has been accomplished. Seven special courses in tropical medicine and parasitology were provided during the year and were attended by nearly 500 Service medical officers. Two week-end courses in industrial health were also arranged. Prof. Greenwood mentions that his own department of vital statistics, while less oppressed by difficulties than some others, has suffered because ordinary sources of information have dried up, owing to security reasons, the impossibility of taking a Census, temporary redistribution in space and occupations of the people, and other causes. It will be a matter of much difficulty, he says, for his successors to prepare an adequate account of the state of the people, and they must give this account to pupils who have not read—and will indeed have had no direct access to—official means of information. The work of the department of entomology has been directed chiefly to serving the needs of the armed Forces in the control of disease-carrying insects, and that of the department of biochemistry to the service of different Ministries, particularly the Ministry of Supply—one matter investigated has been fungal deterioration of Service equipment in the Tropics—with the result that the output of fundamental research has been relatively small. In the department of industrial physiology there has been more opportunity to continue original research, and investigation has been carried out on the heat-insulating properties of clothing materials and on the efficient lighting of schools and dwellings. The outstanding event of the year in the department of public health was the induction of Prof. J. M. Mackintosh to the London University chair in that subject, and the board of management is confident that under his leadership the influence of the school as the Empire centre for the teaching of hygiene and tropical medicine will continue to grow. During the period under review 52 papers by workers at the school were published in medical and other scientific journals.

TREATMENT OF CANCER IN YORKSHIRE

The Bradford and County Joint Cancer Committee, established under the Local Government Act, 1933, and the Cancer Act, 1939, is the first regional body of its kind in this country. The inaugural meeting, held at Bradford on Feb. 20, was fully reported in the *Yorkshire Post*. Of the 30 members of the committee, 10 have been appointed by the Bradford City Council and 10 by the West Riding County Council. The remaining 10 are co-opted, 6 being nominated by the board of management of the Bradford Royal Infirmary, and the other 4 representing the University of Leeds, the voluntary hospitals of Keighley and Halifax, and the medical profession in the area. Under the terms of reference from the Ministry of Health the Joint Cancer Committee becomes the governing body in all arrangements for the prevention and treatment of cancer in Bradford and a large part of the West Riding. In treatment by radium the Bradford Radium Institute will take its part. The Joint Committee will also arrange surgical work, medical work, pathological work, and diagnostic centres. A professional and scientific committee has been set up to advise the Bradford Radium Institute and its new committee of management. The Joint Committee is further responsible for the registration and records of all cancer cases within its area.

The Bradford meeting was followed three days later by a meeting in Leeds of the Yorkshire Cancer Committee, comprising representatives of local authorities, the medical profession, hospitals, universities, and the British Empire Cancer Campaign. Mr. James Phillips, consulting surgeon to the Bradford Royal Infirmary, took the chair. Mr. Bernard Kenyon, clerk of the West Riding County Council, who is acting as secretary to the committee, pointed out that Yorkshire had three radium institutes—at Leeds, Bradford, and Sheffield. For an effective scheme it would be necessary for local authorities to combine, and the good will of the hospitals was essential. The meeting agreed to set up a drafting committee of 18, consisting of one representative for each of the three county councils in Yorkshire, the county boroughs, the British Medical Association, Leeds University, the Empire Cancer Campaign, and the Leeds, Bradford, and Hull Infirmaries. Its proposals for the organization of a comprehensive scheme will be submitted to a further meeting of the Yorkshire Cancer Committee.

Reports of Societies

TREATMENT OF ACUTE MENINGITIS

A meeting of the Section of Neurology of the Royal Society of Medicine, Air Vice-Marshal C. P. SYMONDS presiding, was held on March 1 for a discussion on the treatment of acute meningitis.

Serotherapy and Chemotherapy

Dr. MAURICE MITMAN said that uncertainty about the efficacy of serum in meningococcal meningitis was reflected in the experience of all who had had to treat numbers of cases. Some cases responded satisfactorily, but there were many failures, even in the most favourable circumstances, and this led to the view that not the serum but the spinal drainage was the effective therapeutic measure. Even before the appearance of chemotherapy the popularity of serum had declined. The factors influencing case mortality were: first, the virulence of the prevalent strain of the meningococcus; secondly, the age factor (meningitis under endemic conditions was preponderantly a disease of infancy and young childhood; under epidemic conditions it was widely distributed in all age groups up to 30); and, thirdly, the organization for early diagnosis and prompt and efficient treatment. It was possible to diagnose early meningococcal meningitis on clinical grounds alone in a large proportion of cases. The four cardinal symptoms had been stated by one authority to be headache, vomiting, chill, and rash.

The sulphonamides had transformed the picture. They had reduced the mortality, practically abolished chronic relapsing cases, greatly diminished complications, and shortened hospital detention to 30 days or so. The combination of sulphonamides with serum gave no better results than sulphonamides alone, and in some instances the results were worse. This was surprising, because the modes of action of serum and of sulphonamides were quite different and a synergic action might have been expected. Clinically, however, serotherapy as an adjuvant to chemotherapy had failed, not only in meningococcal but in pneumococcal infections and in certain streptococcal ones. The choice of the sulphonamide had been narrowed as a result of recent work. Sulphanilamide had been largely replaced, though its use was indicated when haematuria was caused by its sister preparations. Sulphathiazole was still largely used, but sulphadiazine or one of its substitution products held the field, being less toxic than the others, except for its tendency to cause crystalluria and haematuria. Routine nursing measures still played an important part in the treatment of meningitis—namely, sedation, adequate nourishment, care of the skin, and watch on the bladder. The place of penicillin in treatment was still uncertain. Eventually it might replace the sulphonamides; at present it was an adjuvant, and sulphonamides were still the drugs of choice.

Treatment by Penicillin

Dr. HONOR SMITH (Nuffield Department of Surgery, Oxford) described 30 cases of pneumococcal meningitis treated by penicillin. About half of them were treated by penicillin alone, and half by penicillin and a sulphonamide. Once pneumococci were seen a lumbar injection of about 20,000 units of penicillin was given, the exact amount depending on the age, size, history, and general condition of the patient. Sulphadiazine was given by mouth or nasal tube, 2 g. hourly, following an initial dose of 4 g. Often for the first 24 hours there was no sign of improvement except disappearance of organisms from the film. Those 24 hours were a period of great anxiety, during which general nursing could make all the difference between success and failure. If the mortality of pneumococcal meningitis was to be reduced to 5% or less, each case must be studied closely and treatment modified in accordance with the needs of the individual. The principles to be followed were: (1) early institution of treatment; (2) administration of adequate amounts of penicillin to all parts of the cerebrospinal pathway; (3) maintenance of adequate concentration of penicillin in the cerebrospinal fluid for a sufficient time; and (4) treatment of primary focus of infection. There was one clinical differentiation between meningococcal meningitis and pneumococcal: in the former it was exceptional to find evidence of a primary focus other than pharyngitis, whereas in pneumococcal meningitis such a primary focus was the rule. With subarachnoid block lumbar puncture became difficult, and this was an indication for resorting to the ventricular or other route for the introduction of penicillin.

Indications for stopping treatment were hard to define. Even in the most straightforward case daily injections should be given for a minimum of five days and withheld only when the patient was obviously approaching convalescence. Relapses were common. The need for a high standard of asepsis in lumbar puncture should be emphasized. As for results, among the 30 cases there had been 8 deaths, but 2 of the patients who died were moribund when the treatment started. Recovery was complete in almost all the patients who lived.

Pharmacology of Penicillin

Dr. E. S. DUTHIE (Sir William Dunn School of Pathology), speaking of the same clinical experiment, said it was always wise to remember that penicillin as received was only about one-third pure. Discretion must be used in treating cases with such an impure compound. The makers were doing their best to ensure the safety of their ampoules, but they could not guarantee it. The dose used in the work just described had been between 5,000 and 10,000 units a day. American workers had used much larger doses, but the dose mentioned had generally given satisfactory results when, 24 hours later, the spinal fluid was examined. Penicillin was now recognized to be a drug which killed bacteria, but it killed them only in the dividing phase, and it did not kill all the bacteria because there was always a small residue not in the dividing phase, which was the reason for the relapses or the positive cultures after treatment had ceased. It had been claimed that with penicillin given intramuscularly clear cerebrospinal fluid could be obtained. The method to be recommended, however, was intrathecal injection, but intramuscular injection might be made in the first instance if full facilities were not available, and by this route some penicillin would pass into the cerebrospinal fluid. He had been told that there was more rapid disappearance of penicillin in older patients, and that was borne out in his own experience. On the other hand, one child aged 17 months lost penicillin with remarkable rapidity. Eventually it was found that she had a large subdural hygroma; after the fluid was evacuated from the hygroma she retained penicillin normally. It had been found advisable to combine penicillin and sulphonamides; the two drugs were better together than either separately, and did not inhibit one another.

Air Vice-Marshal SYMONDS said that the most critical problem was the fulminating case. He asked whether it would be possible for consultants to keep in their bag a small supply of penicillin and rely on it when called to such a case. Before setting out on a consultation they should make more effort to obtain by telephone or otherwise information as to the character of the case so they could have some idea whether it was likely to be acute meningitis. The loss of a few hours might jeopardize the life of the patient.

The Relapsing Case

Brig. HUGH CAIRNS said that the only uncomplicated Gram-positive case of meningitis he had seen after a gunshot wound was in Normandy, where a man who had a wound through the shoulder and the jaw came to one of the neurosurgical units on the beach-head with clinical meningitis. He was treated and recovered. He added that they had been keen to get rid of pneumococcal meningitis from the surgical side. It had been possible clinically to cure the meningitis, but there was relapse as soon as the injection of penicillin into the cerebrospinal fluid was stopped. He had known cases which had relapsed five or six times. It was a diagnostic problem whether the source of infection was extradural or intradural in these relapsing cases. He had been struck during this war by the number of cases of infection of the meninges from either diagnostic lumbar puncture or lumbar puncture for the administration of stovaine, and it was right to say that the standard of lumbar puncture throughout the country was not high enough everywhere to allow this new method of treatment to be contemplated without some degree of anxiety. Apart from serum this was the first time there had been wholesale injections of a foreign substance into the spinal theca, and he wished to emphasize the importance of the most scrupulous technique in the use of lumbar puncture. This was not merely a matter of attention to the particular case when it came along but of organization and preparation and the making of a standard throughout the institution in which one was working.

In some further discussion Dr. **ELI DAVIS** made a plea for the use of sulphamezathine, which, he said, was likely to be less injurious than some of the other sulphonamides. He added that in meningococcal meningitis, although the over-all mortality had been cut down to 10% or less, every now and then there were cases, clinically appearing no different from the others, which slipped through one's fingers, and on post-mortem examination there was nothing to show why this should have happened. One curious thing about pneumococcal meningitis was its uneven distribution. In his hospital he had seen only one case in two and a half years, although at a sister hospital just across the river there had been 80 cases in the same period.

After a number of other comments and questions by Dr. **DONALD PATERSON**, Dr. **HELEN MACKAY**, and others, Dr. **MITMAN** replied on the point of the toleration of sulphonamides by children. A child of 6 would take half the adult dose without difficulty, and a child of 2 would take one-quarter. On the question of mortality and age, while he agreed that there were other factors, he thought that on the whole mortality would be found to vary inversely with age, at any rate up to the later age groups.

CLINICAL PATHOLOGY

The annual general meeting of the European Association of Clinical Pathologists was held in London on Jan. 20, with the president, Dr. S. C. **DYKE**, in the chair.

Prof. E. M. **FRAENKEL** (London) discussed mould allergy in 200 allergic patients. Many more positive skin tests to moulds had been obtained in England (53%) than on the Continent (16%) with an allergen mixture of *Penicillium*, *Aspergillus*, and *Mucor* extracts; he attributed this to the damp climate, which favours the growth of moulds. More recently the moulds used for tests and treatment were cultured from the patients' environment and excretions. Allergens prepared from the six more frequent types (*Sporotrichon*, *Cladosporium*, *Penicillium*, *Aspergillus*, *Mucor*, and *Monilia*) gave positive skin tests in up to 66% of the 200 patients tested with the mixtures and the individual mould allergens. Treatment by desensitization with mould allergens proved to be successful.

Dr. G. **UNGAR** (Paris) described experimental work on the bleeding time; he showed that when several tests were performed on the same individual the bleeding time had a constant value. The bleeding time was independent of blood coagulation, and was mainly determined by the state of the capillaries. Certain facts pointed to an endocrine influence on the bleeding time through the pituitary and the adrenal cortex, which appeared to act on the spleen. From this last organ two factors had been isolated which, when injected into animals, caused lengthening or shortening of the bleeding time.

Dr. R. L. **WORRALL** (Sydney), speaking on aetiology and treatment of influenza, recalled how frequently the nervous system was involved in this disease, and said that these manifestations were probably due to excessive cholinergic activity of the nervous system. In the treatment of these symptoms the main object was to reduce capillary permeability so as to avoid fatal flooding of the lungs with protein-containing fluid from the dilated pulmonary capillaries. To attain this effect he advocated the use of intravenous ascorbic acid and adrenocortical hormone.

NUTRITIVE VALUE OF BREAD

The Nutrition Society held a conference at the London School of Hygiene and Tropical Medicine on Feb. 24 to discuss factors affecting the nutritive value of bread as human food. Prof. R. A. **PETERS**, who presided, said that the need for making the best use of imported grain during the war had led to the introduction of flour of "85% extraction," which meant that this proportion of the milled wheat was recovered as flour. This product made excellent bread, free from fibre, and medical evidence had shown it to be non-irritant, even in patients with ulceration. Unfortunately the 85% standard extraction had now been superseded by 82½%. To reduce the extraction of flour, even if the flour was to be fortified with synthetic vitamins, was a very questionable procedure. Hopkins suggested 40 years ago that numerous organic substances in addition to proteins, carbohydrates, fats, and minerals might be necessary for life and health. Many essential factors besides known vitamins might well be present in the wheat grain. Until we were sure that our knowledge of all the complex constituents of wheat was complete it was unsafe to assume that fractions discarded during milling could be replaced by the introduction of a few known vitamins.

Composition of the Grain of Wheat

Dr. R. A. **MCCANCE** and Miss E. M. **WIDDOWSON**, discussing the superiority of wheat over all other cereals in its bread-making qualities, said that this property was closely linked with its protein content, which averaged 13.62% in "hard" Manitoba wheat with good baking qualities, but only 8.89% in "soft" English wheat, which was poor for baking. Laborious microdissections carried out at the Cereals Research Station of the Ministry of Food had shown that a typical wheat grain consisted of 12.3% of bran, 83% of inner endosperm, 2% outer endosperm, 1.2% embryo, and 1.5% scutellum. The chemical composition and nutritive value of these fractions varied considerably. Thus the endosperm, from which white flour was derived, was rich in carbohydrate; bran was rich in iron; while the embryo and scutellum were rich in protein and fat. The distribution of vitamins also was uneven. Thus the scutellum, a tiny shield of powdery material interposed between the embryo and endosperm, contained more than half the vitamin B_1 of the whole grain. When low-extraction flours were milled the bran included the outer layer of the endosperm, known as the aleurone layer, as well as the germ and scutellum. By suitable modifications, however, flour of 85% extraction might be prepared which contained the germ and scutellum. A reduction in extraction from 100% to 85% involved only a small loss in vitamin B_1, but below 85% the decline was rapid. Dr. McCance deplored the Government's policy in reducing extraction from 85% to 82½%, and also the prospect of further reductions. Only in times of plenty could we afford to give the best part of the wheat to animals.

Dr. **HARRIETTE CHICK**, describing the protein content of different types of flour, said the aleurone layer and germ were much richer in protein than the endosperm, which, however, contributed almost three-quarters of the total protein in the grain on account of its much greater bulk. The proteins of the bran were richer than those of the endosperm in the essential amino-acids—lysine and tryptophane. American workers found that the proteins of wheat embryo were about equal in biological value to those of milk. Dr. Chick herself compared the biological value of the proteins of wholemeal, 85% and 75% extraction flours, by observing the rate of growth of young rats which received these materials as their sole source of protein. Values of 1.6–1.77, 1.54–1.67, and 1.21–1.48 respectively were obtained. Trials by Macrae of the digestibility of the proteins in wholemeal and in flour of 73% extraction gave coefficients of 82.4 and 87.3%. The inferior digestibility of the wholemeal flour did not outweigh the superior biological value of its proteins.

The importance of the method of calculation in working out "biological values" was, however, emphasized by Mr. H. C. H. **GRAVES**, who criticized Dr. Chick's conclusions on the ground that no allowance had been made for protein used up for maintenance rather than for growth. On recalculating Dr. Chick's results with this revision he claimed that her figures indicated no significant difference in the biological values of the protein of the three flours.

Vitamin Loss in Lowered Extraction

Miss A. M. COPPING described the vitamin values of different types of flour. Wheat contained only traces of carotene, although it was rich in vitamin E. Its chief importance as a source of vitamins, however, lay in its high content of the B complex. In biological tests with rats she had found that wholemeal flour contained 1.40 i.u. of vitamin B_1 per g., 2.3 µg. of riboflavin, and 4.0 µg. of vitamin B_6. For national 85% flour the corresponding figures were 1.15 i.u., 2.0 µg., and 3.3 µg., and for 73% white flour 0.35 i.u., 0.85 µg., and 2.0 µg. These figures confirmed the view that while the differences between wholemeal and 85% were trivial, the disparity between 85% and 73% was serious. Chemical estimations by other workers had indicated that the vitamin B_1 content of wheats varied from 2.8 to 8.5 µg. per g. Hard wheats were much richer in this vitamin than soft wheats. The amount of vitamin B_1 included in the flour depended largely on the method of milling. When wheat was moistened before milling the scutellum was removed with the offals, but if the grain was milled dry the scutellum adhered to the endosperm and was included in the flour. Data collected from reports on large numbers of samples of national flour during 1942, 1943, and 1944 showed a steady decrease in the vitamin B_1 and riboflavin content. The change in vitamin B_1 was less marked; this was probably accounted for by the inclusion of Canadian white flour. But the riboflavin content decreased to about two-thirds of its 1942 value. When the extraction was changed from 85% to 82½% at the end of last year the explanation of this change was not clear. According to biological tests little if any of the vitamin value of flour was lost in baking bread.

Dr. R. KODICEK presented the results of chemical and microbiological estimations of vitamins of the B complex in flours, which agreed with the findings of Miss Copping in her experiments with rats. The greatest concentration of nicotinic acid in the wheat grain was in the bran, which contained 235 µg. per g. He suggested that, to avoid confusion, the results of biological tests should be expressed in international units and the results of chemical tests in µg.

Brown or White?

Dr. KENT JONES, in a defence of the policy of "enrichment"—a term implying the addition of synthetic vitamins to low-extraction flour—observed that in the battle between brown and white bread enthusiasts on both sides had recently shifted their ground considerably. The supporters of "brown" bread now realized that wholemeal was not generally popular, that it contained a high proportion of indigestible material, and might increase the tendency to rickets on account of a high content of phytic acid. Those who favoured white flour, while emphasizing that the main function of bread was to provide energy and protein, were alive to the fact that low extraction led to deficiency in certain vitamins. The struggle was, therefore, no longer between wholemeal and ordinary white flour but between 85% "near white" flour and 75% white flour "enriched" with vitamins and minerals. In Dr. Kent Jones's view experience in America had shown that 75% white flour was the popular choice. The loss in nutritive value caused by low extraction was partially recovered by the use of weatings in the production of eggs and bacon. Poorer sections of the population might not, however, be able to afford their full share of these foodstuffs, but for 9d. per person per year 75% flour might be enriched with vitamin B_1, riboflavin, nicotinic acid, and iron, so as to be much superior to 85% extraction flour in these factors. If high-extraction flour was to be endowed by its supporters with the virtue of a high content of unknown vitamins, it may equally well be considered by its detractors to contain unknown forms of phytic acid and other deleterious substances.

Mr. A. L. BACHARACH considered that in deciding between the relative merits of high-extraction flour and "enrichment" it was important to have regard to other matters. A food might be good or bad according to the nature of the remaining components of the diet and other circumstances. Thus Jessop's reports from Dublin suggested that wholemeal bread, while an excellent source of B vitamins, might contain so much phytic acid as to cause rickets. There would be much to commend a flexible policy of combined high extraction and "enrichment," which could be varied to suit immediate needs. Points to be considered in planning "enrichment" were the real need for the supplement to correct a deficiency, uniformity of distribution and stability in the chosen vehicle, compatibility, economy, palatability, ease of estimation for checking purposes, and disclosure to the purchaser. It might sometimes be convenient to add vitamins to foodstuffs which did not usually contain them. Thus in America the addition of vitamin D to flour was permitted.

Prof. FRIDERICIA mentioned that in Denmark, where wholemeal rye bread, with added wheat offals, was freely consumed, the incidence of rickets is not high, while Mr. WOODS reported that the real cause of rickets in Dublin was a shortage in the cod-liver-oil supply which coincided with the period during which wholemeal bread was eaten.

Wheat on the Farm

The afternoon session was devoted to the subject of the rival claims of man and of farm animals and poultry for the coarser fractions of wheat. Prof. H. D. KAY said that the cow was independent of external sources for its B vitamins, which were synthesized by bacteria in the rumen. When not at pasture the cow had to subsist on bulky fodder such as hay, straw, and roots, which must be supplemented by concentrates rich in protein, such as soya-bean cake or decorticated ground-nut cake, in order to maintain milk production. In summer crushed cereals were used as a supplement to good pasture, which was very rich in protein. Weatings were suitable for neither of these purposes, but bran was valuable for making mashes which had a slight laxative effect. The requirements of cows, therefore, placed no obstacles in the way of milling wheat up to 90% extraction for human consumption provided adequate quantities of maize and protein cake could be imported.

Mr. E. T. HALNAN, discussing the value of wheat offals for feeding pigs and poultry, said middlings and bran were staple foods for both, although when given in excess they might impair growth through overloading the intestines with indigestible fibre, and thus reducing the intake of calories. This applied particularly to bran, which should not be given to either pigs or poultry in amounts exceeding 25% of the diet. Diseases indicating deficiency of most of the known B vitamins had already been recognized in hens, as well as a displacement of the Achilles tendon which resulted from deficiency of manganese. When wheat offals were included as a major component of the diet any danger of these deficiencies was avoided. Thus excellent results were obtained in the County Egg-laying Trial with a diet containing 40% wheat middlings and 20% bran. Mr. LE GROS CLARK asked whether poultry could not be given the whole wheat which was saved by the use of high-extraction flour for bread-making, rather than the weatings obtained as a by-product in milling low-extraction flour. Mr. HALNAN replied that whole wheat would not be as rich in vitamins as weatings. Dr. KODICEK suggested that high-extraction flour might well be used for human consumption, and experiments in artificial "enrichment" tried out in the first place on pigs and poultry.

Prof. J. A. S. WATSON disclaimed the idea that "the customer was always right" in regard to flour, and considered that the widespread use of low-extraction flour had harmed the generations which had lived since the invention of the roller mill. During a visit to America he gained the impression that most authorities were in favour of "enrichment" as a practical policy, although E. V. McCollum considered that we could not be sure that all the discarded nutrients were replaced. Economic issues could not be overlooked. The milling of high-extraction flour had meant real hardships to pig and poultry farmers during the war. An increase in extraction from 72 to 82% in the flour used for bread-making, moreover, meant a great reduction in the total demand for wheat. To aggravate the situation bread might be consumed in diminished amounts if not to the consumer's taste. In peacetime, when wheat was not extensively used to make synthetic rubber, the Canadian prairie farmer feared the danger of over-production, which in the past had brought him near to ruin. From a scientific standpoint great hopes might be entertained of breeding improved types of wheat to meet special requirements. Already plant breeders in Australia had introduced drought-resisting types which doubled the yield of grain for every inch of rainfall. In Canada, where the limiting factor was freedom from frost, types of very rapid growth had been employed. There was no reason why wheat specially rich in vitamins should not be bred if this characteristic was particularly desired.

Prof. **Peters**, in his summary, concluded that education was still necessary to persuade the public to prefer bread baked from high-extraction flour. The instruction of bakers in the art of obtaining the best possible loaf was also desirable. The conference had made it clear that cows could easily dispense with wheat middlings, although they required the bran which was usually rejected by the human being. The production of pigs and poultry was certainly handicapped by the diversion of weatings to direct consumption by man, but the "enrichment" of alternative foods for these animals with artificial vitamins seemed worth a trial. The policy of "enriching" flour used for human consumption entailed much greater complications than were at present visualized. Scientific progress might well reveal a "slippery slope" with the discovery of an ever-increasing number of essential nutrients. It might be difficult to restore all these factors to the flour under conditions which would assure their stability.

Medico-Legal

IDENTIFICATION OF GAS CYLINDERS

A tragic accident which occurred at Bath last summer[1] shows the urgent need for adequate and standardized distinction of gas cylinders. A child aged 2½ years was undergoing an operation under nitrous oxide and oxygen. The anaesthetist examined the machine and was satisfied that it was in order, but she did not examine the cylinders. Apparently it was the practice for her to rely on the nurse whose duty it was to change the cylinders. The child stopped breathing and the anaesthetist gave what she thought was pure oxygen, but the child died. She then found that a nitrous oxide cylinder had been coupled up to the oxygen tube. The necropsy confirmed that the child's death was due to asphyxia caused by nitrous oxide. The nurse said that before the operation she had found the two oxygen cylinders empty and had replaced them with two cylinders which she had thought contained oxygen and which she took from a cupboard. She was accustomed to the work, but admitted that she could not have checked the cylinders properly.

Our contemporary rightly comments that, although the anaesthetist ought to have checked the contents of the cylinders, every possible automatic safeguard ought to be used to lessen the risk of such accidents. In these days, as the anaesthetist herself remarked in evidence, it is not very easy to recognize the difference between the two kinds of cylinders. At present anaesthetic gas cylinders are painted black and identified merely by a pasted-on paper label. In transit they are exposed to friction, dirt, paint, rust, and weather, and the labels often become almost illegible. Admittedly oxygen cylinders have white nozzles and nitrous oxide cylinders black, but the difference tends to diminish with time and exposure, and the cylinders are not always kept in well-lit stores. What is required is an unmistakable mark carried completely round the cylinder—e.g., a transverse stripe or stripes of different colours, perhaps made of plastic paint let into shallow grooves. It should be quite practicable to distinguish cylinders by painting the bodies one colour and the stripes another. Accidents due to this cause are unfortunately not rare, and if the anaesthetists would agree upon standard markings, doubtless manufacturers would at once meet their wishes.

Nova et Vetera

CALCAR, WESEL, AND VESALIUS

At the moment when these lines are being written the might of modern battle is thundering within sight of Wesel and the Wehrmacht is striving to save the important Rhine crossing. Five days before the Allied army had passed through the pleasant little town of Calcar. These two places are connected by a road which will now be crammed with military traffic, and through the centuries they are linked by their indirect association with the anatomist Vesalius.

Wesel is situated strategically at the confluence of the Lippe with the Rhine. It has been a stronghold from very early times. The Romans fortified it first, and in his campaign against the Saxons Charlemagne made it his headquarters. Later it was a member of the Hanseatic League, and remained a free imperial city until the sixteenth century. Invaded four times during the seventeenth century, and again in 1805, it once more appears to be living up to its history and its name. The legend goes that after the Roman conquest it was invaded daily by weasels which came from the forest near by, and that this is the real derivation of its name (in Flemish, weasel is *wesel*).

Jan Stephan van Calcar

The ancestors of Andreas Vesalius originally came from this town, and the family name was variously spelt Witing, Witting, Wytinck, or Wytings. Later they moved to Nijmegen, and as so often happened became known from their place of origin as Wesel or Wesalius. The immediate ancestors of Andreas were all connected with the healing art. His great-great-grandfather wrote a commentary on Avicenna; his great-grandfather was physician to Mary of Burgundy, as also was his grandfather. In addition the latter was a writer on medical subjects and a mathematician. The father of the anatomist was apothecary to Charles V. When Andreas *père* and his wife Isabella Crabbe moved to Brussels is unknown, but at any rate it was there that Vesalius was born. On the title-page of his first book—*Paraphrasis in Nonum Librum Rhazae*—he styles himself "Andrea Wesalius Bruxellensis," and subsequently this designation always appeared after his name. The town had adopted as its armorial arms a shield bearing three weasels, and this had been granted to—or assumed by—the Vesalius family. It is there for all to see, high up above his head, in the imaginary theatre so brilliantly depicted in the title-page of the *Fabrica* (1543). *Meae mustellae*—my weasels—he calls them in his letter on the China root. Yet even to his contemporaries his connexion with Wesel could not have been obvious, as we would expect it might have been. Looking at this coat-of-arms we notice the long legs and necks of the three animals. They could only be greyhounds, and even in 1646, eighty-two years after his death, a writer described his coat-of-arms as consisting of three yellow greyhounds on a red field. In the second edition (1555) of the *Fabrica* the graceful animals have been treated surgically, to become what they were originally intended to be—the three weasels of Wesel.

We do not know how often Vesalius visited Wesel during his early life—which is, after all, the only part of his life that matters to posterity—but we do know of one occasion on which he did so. After the publication of his great work in 1543 he took the drastic step of burning his papers and books and becoming surgeon to the Emperor Charles V. Early in January, 1546, Charles opened the Congress of the Order of the Golden Fleece at Utrecht, and proceeded with his train to attend the Diet at Regensburg. When they reached Nijmegen the Venetian Ambassador was taken seriously ill, and Vesalius had to stay behind to attend to him. Perhaps he did not mind the month which he spent there; it certainly gave him the opportunity—as he tells us—of paying a visit to Wesel.

This burning of the books, this forsaking of the anatomy room for the Emperor's court, has been a bone of contention among scholars. It has been said that Vesalius threw away the substance for the shadow. There is little doubt that he was grieved at the way in which the *Fabrica* was received by the die-hards, and this probably was the factor which determined the time at which he took the step. Looking at his ancestry one would think that his parents would naturally desire him to achieve eminence in court circles. That was something which they—with their ancestry—could understand. His father did not die until 1546. Though Vesalius was not one to be swayed by men, it seems quite likely that he had set out with the intention of following the career in which his ancestors' names and his father's influence at court could help him. The introduction to the *Tabulae anatomicae* tells us much. The *Fabrica* may have been an adventure on the way.

Calcar, fifteen miles or so from Wesel, is almost quite undistinguished. It always was what, to quote Christopher Buckley, it was before the war, "a pleasant little country town . . . with a population of some 10,000 or 12,000, strongly Catholic." It would be quite undistinguished were it not for the fact that it was the supposed birthplace of its most outstanding son, usually known as Jan Stephan van Calcar—or various Flemish or Latin equivalents of that name. In Italy he was called Giovanni di Calcar Fiamingo—the Fleming. Calcar was born in 1499, and was thus fifteen years older than Vesalius. He studied art in the school of Jean de Bruges, and apparently as the result of an *affaire de cœur* he appeared in Venice about 1536 or 1537. Practically all we know of Calcar is derived from the pages of Vasari. The *Lives* appeared first in 1550, four years after the death of Calcar, and contained no reference to him. In the second edition (1568) Vasari said:

> "In the year 1545, I became known to, and contracted much friendship with Giovanni Calcar, a Flemish painter of great merit, who so successfully practised the Italian manner, that his works were not always perceived to be those of a Fleming; but he died at Naples, while still young, and when the fairest hopes had been conceived respecting his future progress."

For all his defects Vasari is still the greatest contemporary source of information on the artists of the classical period; and what he says here appears to be true. In the space of about eight years Calcar seems to have assumed to perfection the mantle of an Italian painter; or, in the words of Ivins, to have done what few, if any, other Northerners ever succeeded in doing—absorbed completely the three-dimensional draughtsmanship of Titian and his school. The paintings by Calcar which have survived are not numerous. There was a *Mater dolorosa* in the Boisserée Collection; a portrait of Cardinal Colonna, formerly attributed to Holbein, in Rome; and a number of supposed portraits of Vesalius, in London, Paris, Oxford, Glasgow, and Boston, of which some are probably by Calcar, but none is a genuine portrait of Vesalius.

Calcar seems to have met Vesalius in Venice about 1537, and the result was the publication of the six "fliegende Blätter" known as the *Tabulae anatomicae* (*sex*). In the introductory dedication Vesalius indicates that the first three sheets of drawings are by himself, while the three skeletons are by Calcar. These skeletons struck an entirely new note, and at a bound raised the standard of osteological illustration. Whatever was the reason, Calcar appears to have paid the bill for the publication, whether as agent for Vesalius or because Vesalius needed his financial help is unknown.

The next great works in which the names of Vesalius and Calcar are traditionally linked are the *Fabrica* and the *Epitome*, both published in 1543. For some unaccountable reason the drawings in these volumes—or at least the full-page tabulae—were ascribed to Titian for more than 200 years after the publication of the books. Bonavera (1670) and Tortebat (1667) both believed that Titian was the artist. In 1706 Moschenbauer of Augsburg issued an anatomical work based on Vesalius, in the title of which the statement was made that the figures were drawn by Titian. Considering how often the tabulae of the muscles are found to have been torn out of copies of the *Fabrica*, we might guess that this ascription of the drawings to Titian accounted in part for the popularity of the book. The ascription is strange, since Vasari had written in 1568:

> "Among those about Titian meanwhile was a certain Giovanni, a Fleming, who became a good master, whether for larger or smaller figures, and in portraits was most admirable, as may be seen by his works at Naples, where he lived for some time, and where he ultimately died. By his hand, and they must do him honour to all time, were the designs for anatomical studies which the most admirable Andrea Vesalio caused to be engraved on copper and published with his works."

This is emphatic, and Vasari's many readers would apparently find little to quibble about here. The "operative word," as we might say, which should have set all heads nodding and tongues wagging is Vasari's statement that the illustrations were engraved on copper. It is well-known that the whole of the illustrations in both the *Fabrica* and the *Epitome* were printed from wood-blocks. These blocks were still in existence just before the present war, and the New York Academy of Medicine used them all to reprint the illustrations of Vesalius in a sumptuous volume. Vasari must have known the difference between prints made from wood and from copper, and we are led to wonder therefore whether he ever saw the books.

This is no place to embark on discussion of the identity of the artist or artists who drew the Vesalian illustrations, but a few points will suffice to show the pitfalls in this apparently clear expanse. In the first place, roughly 280 wood-blocks were used in printing the *Fabrica*, and none of them bears the signature of Calcar. Then there is the complaint of Vesalius that he had had difficulties with "several artists," who made him pay dearly for the cutting of the wood-blocks. Of course, there is no reason to suppose that, even if Calcar made all the drawings for the blocks, he also carried out the cutting. Finally, there is the doubt which Vesalius himself expressed in the Venesection Epistle published in 1539: "Wherefore, if there are opportunities of obtaining bodies, and if Jan Stephan—the most illustrious painter of our time (*insignis nostrae aetatis pictor*)—does not refuse his services, I on my part will by no means shun the task." This was fulsome praise while Titian and certain others were still living, and was obviously written for a purpose. Vesalius gave due credit to Calcar in the *Tabulae anatomicae*; yet his name does not appear in the whole of the *Fabrica*. Having embarked on his great task, did Vesalius find that the artist of his choice would not collaborate?

The portrait of Vesalius which adorns all complete copies of the *Fabrica* is generally regarded as being the work of Calcar. This portrait was reproduced in the *Journal* on the occasion of the quatercentenary of the publication of the *Fabrica* in June, 1943. Prof. Charles Singer has recently advanced the theory that, while the head itself is a genuine work of some good artist—Calcar or another—the setting is the work of an inferior craftsman, perhaps the woodcutter. The title-page of the *Fabrica* is almost certainly by Calcar, and it represents one of the finest wood-cuts of all time.

We can sum up briefly by saying that, while the association between Jan Stephan and Vesalius—Calcar and Wesel—is definite, the association between Jan Stephan and the *Fabrica* is another matter.

E. A. U.

W. P. Boger (*Amer. J. med. Sci.*, 1944, **208**, 708), who records two cases in women aged 24 and 52, states that the arthritis commonly described in meningococcal infections is in most cases an acute synovitis which usually accompanies the rash. Acute synovitis as a rule promptly subsides with complete restoration of function, but exceptionally the synovitis leads to a purulent arthritis.

Correspondence

Aerial Infection

SIR,—Dr. Maurice Mitman (Jan. 20, p. 71), reviewing the subject of aerial infection, assumes that the so-called droplet nuclei are the chief factors in the spread of intramural infection. If he will refer to a paper I published four years ago (*Canad. publ. Hlth. J.*, 1940, p. 539) dealing with the transmission of haemolytic streptococcal infections by carriers, he will find: first, an account of experiments showing that when talking or coughing both mouth saprophytes and streptococci are expelled inside heavy droplets, which rapidly fall under the influence of gravity and probably never become droplet nuclei; secondly, an account of many experiments designed to show that droplet nuclei are infected, all of which showed that they are not infected with mouth saprophytes, let alone haemolytic streptococci; and, thirdly, the enunciation of a theory that this type of infection is transmitted by an indirect route, the organisms being expelled by the donor when speaking, coughing, snoring, etc., inside heavy droplets, which fall on to whatever is below the level of his mouth (clothes, desk, table, sheets, pillow-case, etc.), quickly dry thereon, and are subsequently released into the atmosphere on dried particles of dust, fluff, etc., when the surface is disturbed.

The carriers in these experiments were talking or coughing. Subsequent work, which has not yet been published, has shown that the droplet nuclei left floating in the atmosphere after a sneeze may be infected. But if the transmission of these infections requires droplet nuclei it is difficult to believe that we must wait for a sneezing donor before we can get other cases of scarlet fever or tonsillitis. And in any event the demonstration by Thomas and Van den Ende (*British Medical Journal*, 1941, **1**, 953) that the bedding of patients with tonsillitis is heavily infected with haemolytic streptococci, and that these organisms are released into the air in great numbers when the bedding is disturbed, shows that it is only too easy to get the specific organisms into the atmosphere by the indirect route postulated above. Undoubtedly the same thing occurs with carriers, for I was able to show in another paper (*Lancet*, 1941, **1**, 85) that they too can infect their clothes and bedding. For these reasons it is hardly necessary to invoke infection of droplet nuclei to explain the transmission of haemolytic streptococcal infection.

Carriers of other varieties of organisms (*C. diphtheriae, N. meningitidis, H. pertussis*, pneumococcus) have not, so far as I am aware, been studied by this technique, nor have carriers of virus infections such as influenza, smallpox, chicken-pox, measles, or mumps—for obvious reasons. It is therefore impossible to say whether the droplet nuclei expelled when coughing, etc., are infected or not. The chances are that they are not, because even when an indicator organism such as *Ch. prodigiosum* is taken up in large quantities into the mouth this organism too is only expelled inside heavy droplets, although it *may* be present in droplet nuclei when the subject sneezes.

As in the case of scarlet fever and tonsillitis, it is equally difficult to believe that if these diseases are spread by droplet nuclei, diphtheria, mumps, whooping-cough, pneumonia, influenza, smallpox, chicken-pox, measles, will be transmitted only if the donor is good enough to sneeze.—I am, etc.,

University of Toronto. RONALD HARE.

Shock Therapy and Conditioned Reflexes

SIR,—Dr. H. N. Hardcastle makes the interesting suggestion that human behaviour may be regarded as a complex of engrams, a view which appears to me not only to fit the facts but also to bring the Pavlovian conditioned reflex into its right place in the cortical neuronic pattern. But is it necessary to regard the influence of emotion as the primary cause of the engram as a complex of conditioned reflexes? Surely not. As I emphasized in my original address, cortical neurones are constantly being altered by the environmental stimuli to which they are subjected. Hence the engrams, or combinations of neurones, are as constantly being modified—new combinations adding to or replacing older ones. There is more to the engram than emotion, as I sought to explain by referring to the neuronic conception of dreams and the vagaries of memories.

I am not competent to discuss the clinical nature of shock therapy, but if, as Dr. Hardcastle surmises, it will recondition a reflex in the absence of the conditioning factor I see no structural reason why it should not. What ordinary environmental stimuli undoubtedly do, so surely may the violence to which shock therapy submits the brain. It is indeed quite possible that it destroys old engrams and creates new ones. If so, then there is afforded an explanation of the altered behaviour reactions which may follow the treatment.

If this conception of interrelated associational neurones—that is, cortical engrams—satisfactorily explains the vagaries of memory, dreams, Pavlov's conditioned reflexes, and the beneficial influence of shock therapy, then it would appear that we now have a common factor worthy of extended study and application. It is up to those who think otherwise to produce a better explanation, but it will not be easy to contravene the scientific basis of the former.

The conception of the engram at least holds out hope for the future, and I therefore agree with Dr. Hardcastle that it should not now be overlong before there may be evolved a form of therapy in which the "recall" properties of shock may be combined with the selective facilities of the more orthodox psychological approach, though not necessarily the better founded on fact.—I am, etc.,

University Club, Liverpool. RICHARD J. A. BERRY.

Therapeutic Illness?

SIR,—Dr. Narasimha Pai's article on changes in personality after cerebrospinal fever (March 3, p. 289) has evoked the unforgettable recollection of an experience in reverse—an example possibly unique at any rate surely exceedingly uncommon.

During the last war when in charge of a medical division I was informed by one of my juniors of the arrival in hospital of "that perisher De C.," his admission coinciding with his impending departure over-seas. Private De C. had gained (and thoroughly earned) an unsavoury reputation in his unit for slackness and inefficiency; and as he had on two previous occasions succeeded in gaining admission to hospital by reporting sick when on draft for over-seas, his third appearance in similar circumstances not unnaturally excited some suspicion. Proceeding to the ward with the intention of summary action, I found Private De C. with a temperature of 104° F. suffering from cerebrospinal fever, complete with "spots." In those days when our treatment was limited to lumbar puncture and the dubiously effective administration of serum, recovery of such a severe case was no small achievement; yet Private De C. weathered the storm, and after convalescence returned to his unit. I subsequently learnt from his company commander and medical officer that he developed into an exemplary smart and, capable soldier, who, in due course, went abroad enthusiastically and served with considerable distinction.

Encephalitis lethargica is even more notorious than cerebrospinal fever as causative of moral deterioration. Has anyone ever encountered a reversal of character from bad to good in one of the afflicted?—I am, etc.,

London, W.1. ADOLPHE ABRAHAMS.

Ovariotomy or Caesarean Section?

SIR,—What, presumably, Prof. S. J. Cameron (March 3, p. 307) wishes to convey is that for ovarian cysts obstructing, or likely to obstruct, labour he advocates ovariotomy, followed by spontaneous or assisted vaginal delivery rather than ovariotomy followed (or, possibly, preceded) by Caesarean section. His object in writing is, he states, to ascertain if this is the practice adopted by his colleagues.

I can speak best for south of the Tweed, where, I believe, the practice of removing the cyst followed by vaginal delivery has for many years been the established one. It was taught by the late Dr. Herbert Spencer, whose influence was, and is, rightly great. There are, naturally, exceptions: sometimes a wedged or adherent cyst cannot be shifted from the pelvic cavity before the uterus has been emptied, and sometimes accompanying obstetric conditions, which need not be detailed.

indicate Caesarean section. I have never yet known or heard of a case of haemorrhage from the stump.

In the textbook which, I am credibly told, is the one most widely read in these southern climes (*Textbook of Obstetrics,* by Eden and Holland), the advice given is as follows: (*a*) Ovariotomy during pregnancy (at or near term): "Caesarean section is unnecessary unless the tumour is adherent in the pelvis. In all ovariotomies during pregnancy the pedicle should be ligated with extra care and as far away from the uterus as possible." (*b*) Ovariotomy during labour: "After the tumour has been removed Caesarean section is unnecessary, for there will now be no obstacle to delivery by the natural passages. When the operation has been performed towards the end of the first stage, the cervix being dilated, delivery can be immediately completed with forceps, whilst the patient is still under the anaesthetic; if the cervix is not fully dilated labour must be allowed to continue until it is, and then the child is delivered. The presence of a recent abdominal wound does not interfere with natural labour; pain is relieved by morphia, and forceps are applied as soon as the second stage begins."—I am, etc.,

London, W.1. EARDLEY HOLLAND.

SIR,—I should like to support the views expressed by Prof. S. J. Cameron (March 3, p. 307) on Caesarean section in pregnancy complicated by ovarian cysts. I have before me notes of twelve recent cases of pregnancy complicated by ovarian cysts. In one of these I performed Caesarean section. In this case I was unable to control by sutures the bleeding from veins in the uterine end of the attenuated broad ligament. Retraction of the uterus after it was emptied promptly stopped the bleeding.

Haemorrhage from the stump has not occurred in any of the cases. I would suggest that where it does happen it is more likely to be due to faulty technique in ligaturing than to the strain of labour. If this is true the risk of stump haemorrhage will not be reduced by performing Caesarean section.

If any criticism can be aimed at Prof. Cameron's advice in the case quoted in para. 2 of his letter it is that he advised ovariotomy when, considering that it was a dermoid, partial resection with conservation of ovarian tissue might have been possible, as was shown some time ago by Mr. Victor Bonney and more recently by Mr. Scott Russell in your issue of Feb. 24 (p. 262) and by myself in the *Practitioner* (February, 1944). If this could have been done there would have been no stump to worry about. This method is applicable not only to dermoids but to all types of benign ovarian cysts, as I hope to show in a future paper on the results of 50 such operations that I have performed. The fact that the patient is pregnant or is in labour adds but little difficulty to the operation. I consider that wounding the uterus simply in order to deal with an ovarian cyst is quite unjustifiable, and the only occasion on which I have found it necessary a fault in my own technique was responsible. Some cysts lie deep in the pelvis, and their inaccessibility is put forward as an excuse for Caesarean section in such cases. Personally I prefer to eventrate the uterus even though it means making a longer incision in the abdominal wall.

Some years ago Prof. Cameron's colleague Prof. Munro-Kerr pointed out that the mortality of ovariotomy is much higher than most gynaecologists imagine—4%. Why, then, add to this the risks of Caesarean section?—I am, etc.,

Newcastle-upon-Tyne. STANLEY WAY, M.R.C.O.G.

Problems of Cortical Hyperadrenalism

SIR,—When by analogy with "hyperthyroidism" the term "(anterior) hyperpituitarism" had been introduced for pituitary gigantism and acromegaly, it became clear after some years that this must be changed to "(anterior) eosinophilic hyperpituitarism" to differentiate it from "(anterior) basophilic hyperpituitarism"—Cushing's syndrome.

Should cases of "cortical hyperadrenalism" likewise be divided into two classes: (1) the well-known class in which excessive action of the cortical endocrine cells (whether the result of a malignant or non-malignant endocrine tumour of the cortex or of mere hyperfunction of the cortex without any actual endocrine tumour) produces virilism; (2) the much rarer cases in which it produces feminism?

In a case shown to me in 1915—a man aged 27 years, to which my then surgical colleague, Dr. zum Busch, afterwards allowed me to refer (*Brit. J. Derm.,* 1926, **28,** 7)—feminism in the form of bilateral mammary enlargement (a few drops of milky fluid could be squeezed from the nipple of either breast) occurred as the result of an adrenal cortical endocrine tumour. I first thought that this was the only example of the kind on record, but the publication of the Bittorf-Mathias case was earlier (*Virchows Arch.,* 1922, **236,** 466), and since then two or three well-authenticated analogous cases have been recorded.

The question has therefore naturally arisen whether there may be an adrenal cortical hormone (*a*) with a feminism-producing function, like folliculin, as well as (*b*) a virilism-producing hormone like testosterone and the active principle of andreioblastomata in females. If those who hold this view are correct, we already can refer to rare instances of feminism-producing cortical hyperadrenalism (with or without actual tumour-formation) in males (as referred to above); but are there analogous cases in females? May there not be mild forms of feminism-producing cortical hyperadrenalism in females (probably without any actual cortical endocrine tumour) to account for some cases of excessive development of the uterus (perhaps with early and excessive menstruation and myomata) and possibly exaggeration of breast development and secondary female sex characters? Dr. G. Samson, in a conversation, has even suggested to me that the feministic features of so-called "pituitary obesity" and Fröhlich's "dystrophia adiposo-genitalis" in both boys and girls might conceivably partly be due to excessive formation of such a feminism-producing adrenal cortical hormone.

It is clear that the above suggestions are only theoretical explanations. In the same way, it might be suggested that an active thymic endocrine tumour or delayed involution of a large thymus in a young male might cause either excessive virilism of the macrogenitosomia type or, still more rarely, feminism with gynaecomastia and smallness of testes and penis, and that this might be accounted for by assuming the existence of a virilism-producing thymic hormone dominating in the former cases, and a feminism-producing thymic hormone in the latter. But other explanations seem more probable (Weber and Wohl, *Med. Press and Circ.,* 1944, **211,** 22; Weber, ibid., p. 155).—I am, etc.,

London, W.1. F. PARKES WEBER.

Ludwig's Angina

SIR,—Ludwig himself pointed out that *the* danger of the angina now inseparably linked with his name was sudden oedema of the glottis. Obviously, if the larynx is intubated the principal danger of the condition and the anxieties connected with the anaesthetic fade into insignificance. Majors John Farr and E. D. Stanhope (March 3, p. 295) advocate intratracheal anaesthesia in Ludwig's angina.

Even an anaesthetist highly practised in laryngeal intubation requires the patient to be deeply anaesthetized before he can pass a tube beyond the vocal cords. Even a practised intubator has difficulty in regularly intubating the normal larynx blindly, and has to resort to direct laryngoscopy in a percentage of cases. If, as is always the case in true Ludwig's angina, the patient has trismus, a grossly swollen tongue, is "full of mucus," and, above all, has some oedema of the glottis, what chances are there of successful visual intubation if blind intubation fails?

I used to consider that intravenous anaesthesia was the one of choice, but here again all is well only if the mouth can be opened freely. In my experience the only safe anaesthetic for use in Ludwig's angina is local. To perform bilateral local regional block anaesthesia it is only necessary to have a lumbar puncture needle and some 1% novocain. After raising a weal in the skin the lumbar puncture needle is inserted up to the base of the skull behind and parallel to the posterior border of the sternomastoid at a depth of approximately half an inch. Ten to 15 c.cm. of novocain is then injected *as the needle is withdrawn slowly.* This renders the submaxillary region sufficiently anaesthetic for a bowed incision and thorough division of the mylohyoid muscle. When the mylohyoid has been completely divided, the closed fascial space surrounding the submaxillary salivary gland is decompressed, and the danger of oedema of the glottis is circumvented. To save the life of the patient, division of the mylohyoid is, I believe, the only absolutely necessary surgical measure.

It so happens that I am well practised in removing the submaxillary salivary gland under local analgesia, having done this more than 80 times. In two cases of Ludwig's angina, after dividing the mylohyoid freely, I supplemented the regional block anaesthesia with a little local infiltration of novocain, and removed the submaxillary salivary gland, completing the operation by packing the resultant cavity lightly. Certainly both patients had the benefit of sulphonamide therapy; even so, I consider the absolutely unhindered drainage of the infected fascial space accounted for the fact that both patients were virtually convalescent in a few days.

Whether or not those who have made a special study of the surgery of the bucco-cervical region approve of the above measures, I am sure they will support my statement that an incision leading from the mouth into the neck should be avoided on every possible occasion. Ludwig's angina is no exception, and on this account I consider that the incision described in the older literature and advocated by Majors-Farr and Stanhope is a retrograde step.—I am, etc.,

London, W.1. HAMILTON BAILEY.

Nephrectomy with Partial Resection of the Other Kidney

SIR,—The long-range effect of removing more than half the kidney substance has been so seldom observed that a short note on a case about eight years after operation may be of statistical value.

The patient had calculous pyonephrosis and functionless kidney on the left side. On the right side there was a branched calculus occupying the lower calyx system. The latter stone was surrounded with pus, but the upper pole of this kidney was healthy. The two operations, which took place in June, 1937, consisted of complete removal of the left kidney together with the lower pole of the right one, a little less than two-thirds of the whole kidney substance being removed. The case was reported in the *Journal* of Aug. 26, 1939 (p. 445).

Almost eight years have elapsed, and the patient, a married woman now 47 years of age, continues to be in perfect health and is fully engaged in all the usual general and social activities. She has never restricted her diet or taken any special precautions except that she usually takes 5 or 10 gr. of acid sodium phosphate a day to maintain the acidity of the urine. There are no symptoms or evidence of infection or recurrence of calculus. *X*-ray examination shows a large disk-like mass instead of the usual reniform organ on the right side. Following the operation there was a small sinus on the left side, which persisted until a year ago and then closed and remained closed.—I am, etc.,

Johannesburg. R. CAMPBELL BEGG.

Soviet Gramicidin

SIR,—Ever since there has been life one form of life has lived upon another form. Plants depend upon the life in the soil; animals and man upon plants. The life in the soil consists of bacteria, fungi, and protozoa, and my investigations lead me to believe that the life needed by plants is that which is obtained from the lytic action of certain micro-organisms upon fungi. I hold the most active micro-organism to be one which I call the *B. proteus anaerogenes*, as it appears to connect the *B. faecalis alkaligenes* to the proteus group of micro-organisms.

This micro-organism, or group of micro-organisms, abounds in all wastes, and is found in greatest abundance in the final stages of sewage decomposition. Its lytic action upon other forms of protein is greater than that of the other bacteria, fungi, and protozoa with which I have experimented. Indeed, since 1938 I have been using the liquor from sewage to break down my bacterial emulsions in the preparation of the vaccines for the prevention and treatment of distemper and influenza.

Fungi may be used in the laboratory for the same purpose, but their lytic action does not compare with that of the *B. proteus anaerogenes*. My attempts to discover the nature of the lytic action have led me to conclude that it lies in the expander action that the two sulphur atoms, which are attached to the pyrimidines—cytosine and uracil—in the nucleic acid, and especially the amino groups of the polypeptides of the live agent, exert upon the dead object. This sulphur-nucleic acid-amino-polypeptide complex is the most important one in the constitution of every protein product. It is the complex in its concentrated form extracted from *Penicillium notatum* which forms the basis of penicillin, and doubtless the one which, extracted from *B. brevis*, forms the basis of gramicidin. But the work I am doing on the *B. proteus anaerogenes* suggests that the complex extracted from this micro-organism might yield even better results. As the complex of the lytic agent extracts the complex from the dead object, use need not be limited to the former but it should be extended to include the latter. Insulin owes its action to the same amino-polypeptide complex, and the sulphonamide compounds owe their expander action to the aniline amino group.

Interesting as it may be to discover the most active polypeptides in the complex, the inquirer must avoid carrying the differentiation too far, because in all these inter-protein reactions the more important agents are the connexions between the chemical substances, and not the chemical substances themselves. In conclusion, I would like to say that man has not touched the fringe of the allied nutritive and therapeutic values of wastes.—I am, etc.,

London, W.1. J. E. R. McDONAGH.

Oral Administration of Penicillin

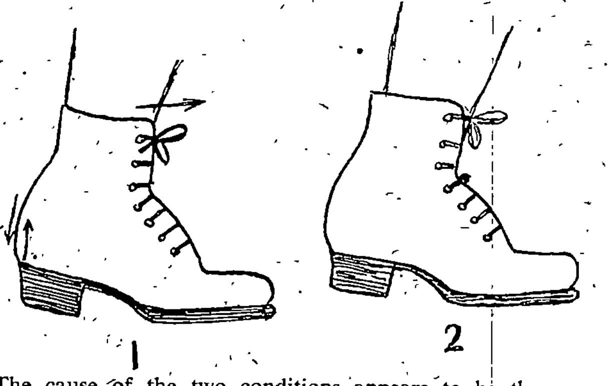
SIR,—In your very timely and instructive annotation on new ways of giving penicillin (Feb. 17, p. 227) you write as follows about the possibility of giving penicillin by the mouth: "This route has hitherto been firmly ignored because the drug is destroyed by acid, and even administration by duodenal tube has resulted in poor absorption." As the importance of a possible oral administration for general practice cannot be over-emphasized, may I suggest that research workers who are in a position to carry out experiments should try to give penicillin in keratin-coated gelatin capsules. These capsules have the great advantage that owing to the insolubility of keratin in acid medium they pass through the actual stomach intact and get dissolved only in the richly alkaline medium of the lower part of the small intestines, freeing their content there.

The administration by duodenal tube is a complicated and difficult procedure not suitable for general practice, and for the actual purpose inferior to the keratin-coated capsules, the alkalinity of the duodenum being a very unreliable factor because it is constantly altered and upset by the unceasing injection of the acid gastric content. Often there is no alkalinity at all, the latter being over-compensated by the hyperacidity of the stomach and thus leading to duodenal ulcer.—I am, etc.,

Newark. L. SCHMIDT.

Prevention of Blistered Heels

SIR,—The article on peritendinitis (Johnson, H. D., *Journal*, 1945, 1, 193) brought to my mind the method of blister prevention given me by an old Swiss guide soon after the last war. After some years of hospital life with very little exercise, my feet could not stand the long mountain walks, and first blisters and then tenosynovitis of the Achilles seriously interfered with the holiday.



The cause of the two conditions appears to be the same. When the ankle is flexed in bringing the hinder foot forward, the rigidity of the laced-up front of the boot is less than the rigidity of the sole; therefore the heel rubs against the leather of the boot, and if the rub is a broad one a blister forms; if there is a wrinkle in the boot heel, tenosynovitis occurs. (Fig. 1.)

I was advised to lace the first four eyelets rather tightly and then make a double twist in the laces, the first part of a surgeon's knot; next twist the lace-ends round so that the end which was going to the right now goes to the left. Instead of this a proper knot may be made, but this takes long to undo. The double twist plus reversal is almost as firm as a full knot and takes no time to loosen. After this, lace on the rest of the boot distinctly loosely. This completely alters the resultant forces. The ankle can now have a little play and the rub due to the rigidity of the sole is almost absent and folds in the leather are not forced against the tendon (Fig. 2).

Since putting this into practice I have had little further trouble and have been able to face the long walks after a year or so of a sedentary life.—I am, etc.,

A. T. Todd,
Physician, Bristol Royal Infirmary.

Repair of the Oblique Hernia

Sir,—With reference to the evergreen topic of hernia, I am rather surprised to find no mention in recent reviews of the excellent procedure for repairing the large oblique hernia devised by Mr. F. R. Brown and reported in the *British Medical Journal* some fifteen years ago.

As Brig. Edwards (*Brit. J. Surg.*, 1943, **31,** 122) so rightly emphasizes, a hernia of this type, in which the neck of the sac has expanded medially, requires considerably more than ligature and removal of the sac at its neck if the cure is to be permanent. In Brown's operation, after removal of the sac, a spiral strip cut from the sac itself is used for the "hammer" method of repairing the defect between the internal oblique and the recurved edge of the inguinal ligament. The length and strength of the material which can be obtained from such a source are quite remarkable; and this procedure obviates the somewhat tedious business of taking a strip of fascia from the thigh.

As a point in technique I think it is important in those cases in which fascia is removed from the thigh that the limb be bandaged immediately with a crêpe bandage over wool. Subsequent haematoma formation, fibrosis, and pain are thus minimized.—I am, etc.,

James F. Riley,
Surgical Specialist, E.M.S.

Tuberculous Infection of Nurses

Sir,—Before the editorial ban falls on this subject, may I point out that Dr. L. E. Houghton's critical letter (Feb. 24, p. 274) does not attempt to refute the arguments of my two previous letters, which relate specifically to the risks to the Mantoux-negative nurse when exposed to infection in tuberculosis wards. I am not concerned with or about Mantoux-positive nurses.

Dr. Houghton admits that the sanatorium nurse is certainly infected during her duties, but apparently questions the significance of massive infection. If massive infection plays no part, then we need no longer take precautions against such infections, patients may cough tubercle bacilli over the nurse indiscriminately, and other precautions be abandoned. Standard teaching on the subject of bacterial infection, however, still accepts massive infection as an important factor in producing disease—e.g., Boyd's *Pathology,* which states that "when small numbers of micro-organisms enter the body they may be destroyed, but if in large numbers they may overwhelm the defence, and tuberculosis is a good example."

No one would deny the importance of environmental, genetic, and immunological factors in the aetiology, but as tuberculosis is known to be an infectious disease (Koch, R., 1882) the fundamental causal factor must be invasion by the specific organism.

It will be interesting to learn the result of the survey of nurses at Market Drayton and Harefield. It would be even better if this survey could extend to other less efficient institutions, where, as Dr. T. F. Bostock has told us (Feb. 10, p. 198), environmental factors may be far from satisfactory. Unfortunately movements of nurses are frequent, their health records may be inadequately kept, and Mantoux-testing is comparatively uncommon; so that short of a planned survey, which will take some years (five or six in Dr. Heaf's estimate), no accurate large-scale information is likely to be forthcoming.

It is for these reasons I suggest that the available evidence on tuberculous infection in general hospital nurses is sufficient to demand the exclusion of Mantoux-negative nurses from all tuberculosis wards, or, alternatively, their immunization.—I am, etc.,

Kinmel Hall Hospital, Abergele. W. E. Snell.

Aetiology of Erythema Nodosum

Sir,—With reference to the article on the aetiology of erythema nodosum by Prof. C. Bruce Perry (Dec. 30, 1944, p. 843) and also your leading article (p. 857), I feel sure that Prof. Perry would take exception to the comment in the leading article, which ventures the opinion that "no one is likely to go far wrong who regards a case of erythema nodosum as tuberculous unless it is proved otherwise." In his conclusions he is most careful to stress the non-specific nature of the toxaemia.

The question naturally arises why there is such a frequent association between the two conditions. It is also necessary to clarify the position as regards the basic causes of the various types of rheumatism. If the position is left as it is we would appear to be heading for another "cause and effect" misappreciation which would result in unnecessary anxiety on the part of those who have had the misfortune to inherit a pituitary discrinism, with its protean manifestations.

When the puling infant, biophysics, attains maturity we shall be required to interpret all clinical phenomena in terms of water, its solutes and suspensoids, and the electrical phenomena induced in them by the omnipresent factor of radiation. The Auckland Research Group have already endeavoured to meet the new situations that will surely arise when the head-on collision eventuates between "electronics" and the ideas and explanations that have largely come down to us from the Middle Ages. All bodily swellings will come to be regarded as electrical water-colloid effects, which arise out of the attraction between negative water molecules and colloid structures that have been rendered positive as a result of the attachment to them of positive toxic molecular entities. It is merely a question as to where the positives come from—i.e., bacterial or metabolic. The life process will be regarded as a radiational water-colloid effect, with the pituitary neuroglandular structure dominating and controlling all enzyme and hormone activities.

Our thinking and reasoning will be dominated by "cause and effect" chains much like the following: (1) constitutional pituitary "wobble"; (2) dysfunction of the somatotropic hormones; (3) a discrepancy between the size of the thorax and the lungs; (4) over-stretching of the lungs by the atmospheric pressure, and resulting emphysema; (5) impaired apical air currents and ciliary defence mechanism; (6) pulmonary tuberculosis. The erythema nodosum chain will also start with: (1) pituitary discrinism; (2) dysfunction of the hormones controlling metabolism; (3) a radiation dysfunction and a consequent impairment of the extrinsic renal factor; (4) impaired excretion of positives, and a lowered negativity of membranes with impaired permeability; (5) dominance of the positive toxic factor in local areas; (6) erythema nodosum. We shall also eventually recognize the dual source of the positives that underlie the blanket term "rheumatism"—i.e., bacterial and metabolic.

So it is that the common constitutional pituitary factor may ultimately lead to effects as far apart as tuberculosis and erythema nodosum. We feel that statistical investigations should be integrated on a wider base and at a lower level, taking in such ultimate pituitary phenomena as hyperchlorhydria and flat feet. Little progress will be made until it has been shown that there is a statistical relationship between effects such as melaena and corns. We would also stress the dangers and sorrows that may arise out of the interpretation of small calcified pulmonary nodules revealed by *x* rays. A dysfunction of the growth hormones, and resulting emphysema of moderate grade, is much commoner than is generally realized, and it frequently does not lead to an impairment of the haemo-respiratory gaseous exchange. It does, however, frequently lead to varying grades of obstruction in the pulmonary circulation, and some degree of raised venous pressure, which is adequately accommodated by the vein valves. This factor of strain not infrequently leads to a deposition of calcium at valve sites (phleboliths).

Until medical science has a much wider and deeper understanding of causes and effects we would be wise to interpret statistical comparisons with caution.—I am, etc.,

Auckland Research Group, New Zealand. W. N. ABBOTT.

Room for Women Students

SIR,—We the undersigned all received our medical education in different medical schools of London voluntary hospitals which at that time were providing co-education—namely, St. Mary's, St. George's, University College, and the London Hospital. In each hospital special accommodation for women students was limited to the provision of a cloakroom and lavatories, and in the case of one or two of them a common room also. For women resident medical officers no special accommodation was provided: bedrooms, sitting-rooms, common rooms, bathrooms, and lavatories were used as they would be in a hotel or boarding-house without any sex discrimination. It would therefore appear that there is no legitimate reason on the score of lack of accommodation for delaying the entry of women medical students into the medical schools and hospitals which are at present reserved for men only. It should not be an insuperable difficulty, even in wartime, to provide a common room (if it is thought necessary), a cloakroom, and lavatory accommodation for women medical students.—We are, etc.,

DORIS G. LITHERLAND, M.R.C.S., L.R.C.P.
MARY MITCHELL, M.R.C.S., L.R.C.P.
DOROTHY HOWSE, M.R.C.S., L.R.C.P.
Bournemouth. PHOEBE WOODWARD, M.B., B.S.

Final M.B. of London University

SIR,—I would like to share in the appeal made by Dr. D. S. Porter (March 3, p. 310) against the unfortunate discrimination involved in the new regulation for the London M.B., B.S. Final Examination. I, too, sat for this examination in the first year of the war, and entered the Army in the same year. My failure in the examination, so I was informed, was limited to the oral part of one subject; and this indeed was the only failure in my student career.

It is presumed that the new regulation has been instituted to make allowance for the increased difficulties of study and examination in wartime. The difficulties of students taking their final examinations in the early months of the war have perhaps been forgotten. My own circumstances at this time are probably typical of those of my contemporaries. I was hastily turned out of my London teaching hospital on the day war broke out and sent to an L.C.C. hospital in the area, there to continue my studies under unavoidably makeshift conditions. I and my fellow students were accommodated in small cubicles incompletely divided from one another; the deficiency of space and inadequate lighting made study almost impossible, yet we were required to live on the premises. The greater part of my time was spent in filling sandbags, transferring patients in Green Line coaches, assisting in the establishment of a blood transfusion centre, and attempting to carry out the more essential functions of the hospital laboratory, from which the entire staff had been suddenly transferred under E.M.S. arrangements. Part of my Final Examination was taken in London and part in Manchester. Finally, it need hardly be mentioned that the general atmosphere at that time was more unsettling and more eerie than it has been in the last few years. Conditions were, therefore, thoroughly inimical to the concerted absorption of those minutiae with which a candidate is expected to be equipped, and it was perhaps more a sign of the times than of ignorance that not all of us were able to reproduce in an orderly and confident manner such facts as we had learned.

If, as I suspect, the new regulation was instituted from a charitable motive, then those of us who attempted our Final Examination in those hectic days, and who have been prevented by national service from resitting our examination until many years later, may surely expect the privilege to be extended to us. After all, it is not a question of seeking to lower the high standard demanded, but merely of being credited with those subjects in which we did, in fact, satisfy the examiners.—I am, etc.,

HAROLD B. HEWITT,
Capt., R.A.M.C.

The Young Married Doctor

SIR,—I agree most heartily with the letters of "Married Doctor," "B1," "Y.M.D.," and Tom Barns, especially where better conditions are likely to produce better work in hospitals, as they do in industry. Hospitals should not only give the permission to live out, as suggested by Tom Barns, but should either provide both living-in and living-out accommodation or give a living-out allowance in lieu to cover a reasonable rent, including the telephone, and food, fuel, and light. The hospital should also have some form of transport to convey the doctor to it at a moment's notice, or provide a further allowance in lieu if he happens to run a car.

If priority were necessary in this scheme, senior resident medical officers and ex-Service officers should have the preference. At present many doctors find the fight for a decent existence detrimental to their primary fight against disease. And I think that most young Service doctors, married or unmarried, resent this association of celibacy with hospital appointments when they turn their thoughts towards the post-war period. Have their careers as doctors not been warped enough already by the conditions of war? A happily married doctor is better than a happily unmarried one who has merely resigned himself to an unnatural and prolonged non-marital state—or fate. Sacrifice is often necessary in the life of a doctor, and if he is true to his calling he never flinches from it, but surely marriage is one thing which he should not have to sacrifice when he takes the Hippocratic Oath, especially when the great Hippocrates taught that disease was due to disobedience of natural laws.

It is more than pleasing to see that this subject has come to the notice of the medical public, and possibly also to some of the non-medical hospital public, by courtesy of your columns. —I am, etc.,

N. Ireland. "Y.M.S.O."

Artificial Respiration

SIR,—My committee's attention has been called to several articles appearing in your *Journal* in connexion with the Eve rocking stretcher method of artificial respiration, and they note particularly the remarks made by Dr. F. C. Eve in your issue of May 1, 1943 (p. 535), as to the inadequacy of the Schäfer method and the attitude of complacency adopted by the Royal Life Saving Society in this matter. My committee ask that you will kindly bring the following facts to the notice of your readers.

The Royal Life Saving Society is only too anxious to adopt and teach to the multitude any method of artificial respiration which can be proved superior to that of Schäfer. The society some months ago extended to Dr. Eve an invitation, which he accepted, to demonstrate his method before the members of the Central Executive and a large gathering of experts on artificial respiration, and the doctor was closely questioned upon the merits and demerits of his system. As a result of this demonstration it would appear that the success of his method stands or falls by his own statement that the diaphragm in a deeply asphyxiated person remains, owing to loss of muscle tone, in a permanently arched position, and he stated that he had "no doubt that the diaphragm would go up several inches." This statement by Dr. Eve was challenged, but he agreed that it could be checked by *x*-ray photographs, which Dr. Eve and we have tried to obtain without success.

After further correspondence, in which Dr. Eve was asked for some conclusive proofs of his statement, he has replied in writing that he has no proofs at all. If definite proofs could be produced, no one would be more pleased than the members of the governing body of the society, for they wish it to be known that they have a permanent committee appointed to survey current expert opinion in relation to new methods of resuscitation, with the object of their adoption, if found in any way superior to Schäfer. So far nothing has been discovered to supersede this very well tried and successful method.—I am, etc.,

London, W.1.
ALWYN E. BISCOE,
Chief Secretary, Royal Life Saving Society.

Erythrocyte Sedimentation Rate in Malaria

SIR,—Please allow me to make the following brief addendum to my letter published on March 10.

The differentiation of malaria—of the falciparum type—from sandfly fever at an early stage is important; many cases of this type of malaria have proceeded to "cerebral malaria" and death while being treated for "sandfly." The mortality is also high in cases of falciparum malaria treated as infective hepatitis, unexpected coma giving an indication too late for effective interference. Truly a living problem may prove a dead certainty.—I am, etc.,

FRANK MARSH.

Check your References

SIR,—Dr. C. Langton Hewer (Feb. 17, p. 233) usefully discusses the most convenient method of reference to earlier papers, but makes no mention of the need for accuracy of actual references.

In writing on commission a comprehensive review of radiological progress, I lost much time looking up references because of their inaccuracy. Lawrence in (I believe) his first description of the cyclotron in the *Physical Review* gives due reference to the prior work of Wideroe published in the *Archiv für Elektrotechnik*, but his reference is incorrect and much time was wasted tracking down the original paper. A still more glaring example was about planigraphic (tomographic) methods. Andrews in his excellent paper in the *Amer. J. Roentgen.* (1936, **36**, 575) refers to the work of Portes and Chausse and gives their French patent as No. 541,941 of 1922. Reference to this patent at the Patent Office showed other patentees of a patent having no relation to radiology. Extensive search failed to reveal the Portes patent and, as a consequence, all reference to it was deleted. No assistance could be obtained from other authors as all gave this patent number, including Grossman (*Fort. a.d. Geb. d. Roentgenstrahlen*), Keiffer (*Amer. J. Roentgen.* and *Radiology*), and Twining (*Brit. J. Radiol.*), the inference being that the reference was merely copied with its error. After omission further attempt was made to track down this much-quoted patent, and, after much time in acrobatic feats on the high steps of the Patent Office, it was tracked down to a different French patent.

Having a personal library which comprises journals not otherwise available, I have in the past been asked to supply details of references for papers being published. While doing so with pleasure I have later been surprised to note the amount of information which is presumably obtained from a mere reference only.

Mention of an earlier publication usually infers first-hand acquaintance, but unfortunately it appears to have become the vogue to quote prior papers without actual personal reference as to correctness, etc. It is, of course, quite possible that circumstances are such that a reference is merely quoted for its priority; for example, in dealing with the Ziedes des Plantes method of planigraphy, I personally gave references to his publications in the *Fort. a.d. Geb. d. Roentgenstrahlen* and *Acta Radiologica*, journals moderately easy of access and personally owned, but for priority reasons gave the first publication in a Dutch medical journal not accessible or read by myself. My editor, however, even in this case queried the unusual page number of 5218 and would not include it until this journal had been located and the page number checked.—I am, etc.,

London, E.7.
BERNARD LEGGETT.

Present Practice of Diphtheria Immunization

SIR,—In reply to Dr. Evelyn Maclagan's questions (March 3, p. 309) the ages of the positive Schick reactors were: 2 1/12 (1), 2 3/12 (2), 2 5/12 (1), 2 1/2 (2), 3 (1), 3 1/12 (1), 3 1/4 (1), 3 10/12 (1), 4 (3), 4 1/12 (1), 4 2/12 (1), 4 4/12 (1), 4 1/2 (3).

A Schick test was performed three months after immunization, and *all* were negative.

No mother produced a certificate stating that the whole procedure was satisfactory. (We are issuing one to each mother at this nursery.)

The two children who developed diphtheria (positive cultures) were one boy, aged 4, immunized here Jan., 1943, Schick-negative, diphtheria July 28, 1943, mild case, returned to nursery Sept. 14, 1943; another boy, aged 4 4/12, immunized at L.C.C. school 1941, Schick-negative, diphtheria Aug. 27, 1943, mild case, returned to nursery Sept. 14, 1943.

It is our practice here to carry out a further Schick test after two years and re-immunize positive reactors.—I am, etc.,

Battersea Central Mission.
J. L. BLONSTEIN.

The Services

Col. K. S. Master, M.C., I.M.S., has been appointed Honorary Physician to the King in succession to Col. A. C. Macrae, I.M.S.(ret.); and Col. W. C. Spackman, I.M.S., V.H.S., has been appointed Honorary Surgeon to the King in succession to Major-Gen. R. H. Candy, C.I.E., I.M.S.(ret.).

Temp. Acting Surg. Lieut.-Cmdr. R. N. Martin, R.N.V.R., has been mentioned in dispatches for courage, endurance, and determination in transporting stores, vehicles, and men in L.S.T.s and L.C.T.s and other vessels to the Normandy beaches.

Acting Temp. Surg. Capt. W. B. D. Miller, D.S.C., R.N.V.R., has been mentioned in dispatches for good services in organizing the evacuation of casualties from the forefront of the battle during the liberation of France and Belgium.

L/Cpl. Henry Eric Harden, R.A.M.C., who, after bringing in to safety two badly wounded men, was killed while endeavouring to rescue another, has been awarded a posthumous Victoria Cross.

The following awards have been announced in recognition of gallant and distinguished services in Italy:

D.S.O.—Majors E. H. Anderson and R. W. Boyden, R.C.A.M.C.

M.C.—Capt. J. K. Pugh, R.A.M.C.; Capts. T. C. Hopkins-Husson, S. Anand, and S. R. C. Muthuswamy, I.A.M.C.; Capts H. F. Owen and T. Statten, R.C.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Killed in action in Burma.—Capt. Peter Hamilton Barkey, R.A.M.C.

Previously reported missing, now officially recorded killed in action.—Major Clarence Alexander Calder, R.A.M.C.

Accidentally killed.—Lieut.-Col. Maurice Baylis King, M.C., R.A.M.C.

Died on active service.—Capt. Bernard Alfred Maclean Brown, M.C., R.A.M.C.

Died of wounds.—Capt. Joseph Campbell Swanson, R.A.M.C.

Died.—Flight Lieut. Ernest Alexander Wallis, R.A.F.V.R.

Wounded.—Temp. Lieut.-Col. R. B. Wright, O.B.E., R.A.M.C.; War Subs. Capts. A. R. Elsom and T. M. Rowatt, R.A.M.C.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation on March 2 the degrees of M.D. were conferred on N. H. L. Ridley and of M.B., B.Chir. on G. Hartridge, both by proxy.

During the month of February titles of the degrees of M.B. B.Chir. were conferred by diploma on E. M. Davies, M. Farquharson and M. H. Jordan, of Girton College, and on E. M. Kingsley-Pillers, of Newnham College.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

Dr. Henry MacCormac, F.R.C.P., will deliver the Lumleian Lectures on "Prospect and Retrospect" at the College (Pall Mall East S.W.), on Tuesday and Thursday, April 17 and 19, at 4.30 p.m.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A cheque for £100,000 has been received by the President from Sir William Henry Collins for the endowment of the Departmen of Anatomy and the institution of a Chair of Human and Comparative Anatomy. Last year he gave £100,000 for a Chair of Pathology.

Médecin-Colonel Merle d'Aubigné, Conseiller technique au Ministère de la Guerre, and two other French military surgeons Major-Commandant Toulemonds and Captain P. Lance, were received at the Royal College of Surgeons on March 8 and entertained to luncheon. They brought to the meeting of the Council greeting from the President of the Académie de Chirurgie at Paris, received a cordial welcome, and took back from the President and Council of the College greetings of friendship and an expression of hope that it would soon be possible for normal relations between the two bodies to be resumed.

SOCIETY OF APOTHECARIES OF LONDON

Prof. E. C. Dodds, M.D., F.R.S., will deliver a lecture on "Ancient Apothecaries and Modern Biochemists" at Apothecaries Hall, Black Friars Lane, Queen Victoria Street, E.C., on Tuesday March 27, at 4 p.m. Members of the medical profession and senio students are cordially invited.

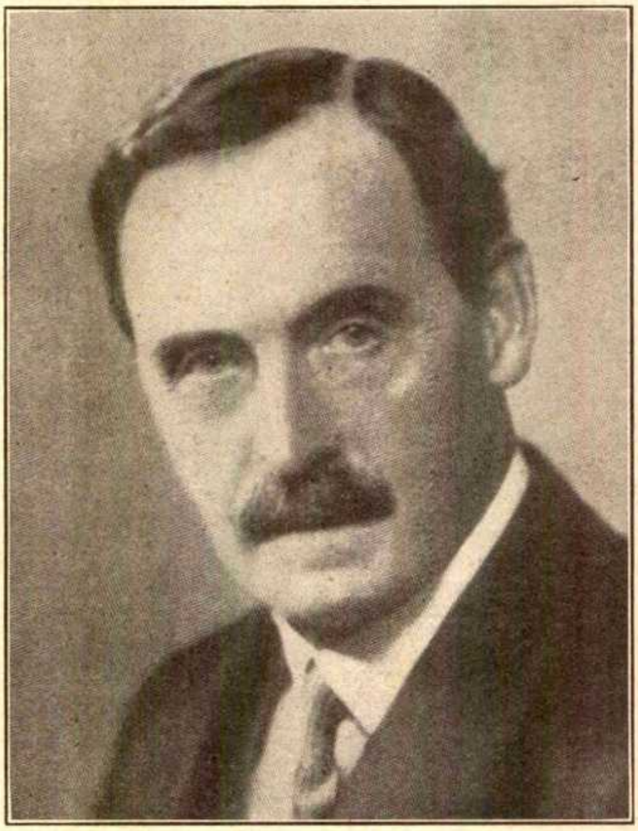
Obituary

VISCOUNT DAWSON OF PENN,

P.C., G.C.V.O., K.C.B., K.C.M.G.

President of the British Medical Association

The death of Viscount Dawson of Penn, which took place on March 7, robs British medicine of one of its most prominent personalities. For a third of a century, during four reigns, he was a physician to the King. For twenty-five years he was a member of the House of Lords and took an active part in its debates. For seven years he was President of the Royal College of Physicians of London. He was twice President of the B.M.A.—the first time at its Centenary Meeting and the second when the Association was about to face all the problems raised by the publication of the Government's White Paper on a National Health Service. During the whole of his professional career he was associated with a great London hospital and its teaching school and the university of which the school is a part, becoming a member of the Senate and for a time dean of the medical faculty. He was equally wise and sympathetic at the bedside, at the teacher's rostrum, and at the council table. Perhaps the greatest thing about him was that, although the offices he held must have inclined him to caution and reticence, he was sympathetic towards forward movements in the science, practice, and organization of medicine, and in social affairs, and never behindhand in proclaiming the faith that was in him. He was also a most likeable man, distinguished in any assembly by his attractive presence, alert manner, and persuasive speech.



Dawson of Penn

Education and Early Career

Bertrand Edward Dawson was the son of Henry Dawson, an architect, of Purley in Surrey, where he was born on March 9, 1864. From St. Paul's School he entered University College, London, where he took his B.Sc. in 1888. A modest man, he was never willing to talk about his career, but there is some indication that the early years were not without struggle. Mr. Ramsay MacDonald, at the annual dinner of the Royal Society of Medicine in 1929, when Lord Dawson was in the chair, mentioned that he and his host had been students together at London University, and that on occasion after a students' supper they would tramp at midnight from Gower Street to their lodgings in Holloway because their combined resources were insufficient to raise a cab fare. Mr. MacDonald added that when next he met his fellow student it was in Buckingham Palace forty years afterwards.

Bertrand Dawson's clinical studies were undertaken at the London Hospital. He was an eager student, and eagerness as a clinician was indeed characteristic of him all his life. He qualified in 1890, and three years later, before he was thirty, took the M.D. of London University. It was at the London Hospital that he held his first resident post; later he became medical registrar and lecturer in physiology in the medical school. His first appointment as an honorary physician was at the Royal Hospital for Diseases of the Chest, City Road, where he also acted as pathologist. In 1896 he was elected assistant physician at "The London," lecturing also on elementary clinical medicine and materia medica, and in 1906 full physician. Long before this his reputation as a consulting physician had become thoroughly established.

During all these years he wrote extensively in medical journals, hospital reports, and textbooks. In 1895 he contributed to the *Twentieth Century Practice of Medicine* a paper on diseases of the lymphatic system. Later he wrote in Allchin's *Manual of Medicine* the articles on diabetes mellitus, diabetes insipidus, influenza, rheumatoid arthritis, and the physical examination of the stomach and intestines. His special interest in medicine at that time was disorders of the alimentary tract. The value of *x* rays in this connexion appealed to him, and one of his early papers, given in 1907 to the former Roentgen Society and well illustrated, was on the *x*-ray diagnosis of stricture of the oesophagus.

Court Physician

In 1907 he was appointed physician-extraordinary to Edward VII, and with the three physicians-in-ordinary he attended that King on his deathbed in 1910. He was also made physician-extraordinary to George V, and at the same time a Knight Commander of the Royal Victorian Order. In 1914 he became physician-in-ordinary. Throughout the reign of George V, extending over a quarter of a century, he was not only medical adviser but a trusted friend of the King and the Royal Family. He came most conspicuously before the public during the King's illness which began at the end of 1928. From the issue of the first bulletin on Nov. 21 until the thanksgiving service for the King's recovery in the following July, he bore a load of responsibility such as has seldom fallen to a court physician. He was assisted by a carefully chosen and most capable "team," as he called them, to whom he made public acknowledgment, but in the eyes of the people it was Lord Dawson who had "pulled the King through." In January 1936, he was at Sandringham during the last days of George V, and signed the bulletin which announced to the nation that the King's life was drawing peacefully to its close. He became physician-in-ordinary again to Edward VIII, to whom as Prince of Wales he had been physician since 1923, and after the abdication he remained the head of the medical advisers of George VI. He was also physician-in-ordinary to Queen Mary.

War Services

At the outset of the war of 1914–18 Sir Bertrand Dawson, as he then was, held a commission in the R.A.M.C.(T.F.) as commandant of the 2nd London General Hospital. Later he served as consulting physician to the British Armies in France, attained the rank of major-general, and became honorary member of the Army Medical Advisory Board (of which many years later, in 1936, he was chairman). Among the clinical subjects in which he interested himself during the war were paratyphoid fever and jaundice of infective origin. In 1915 he led a special investigation into the causes of infective jaundice among the troops in France, cases of this nature being collected in a special hospital. In an elaborate paper on the subject, which was published in this *Journal*, Sir Bertrand Dawson, with two collaborators, showed that the type of infective jaundice there seen was the same in its clinical and pathological features as had just been described by Japanese workers as due to the presence of a spirochaete in the liver.

His duties as consulting physician to the British Armies in France took him to all the war hospitals, British and American. Some years afterwards, in addressing McGill University, the first to send a fully equipped hospital to the seat of war, he mentioned that that hospital had been in his zone of work, and how immensely his visits to it had inspired and cheered him.

The Ministry of Health

As the war came to an end Sir Bertrand Dawson began to call the attention of our profession and the public generally to the position of medical services in the approaching period of reconstruction. He was a prominent member of a committee set up by the British Medical Association to formulate a scheme for the establishment of a Ministry of Health. He set forth his own proposals under this head in his Cavendish Lecture before the West London Medico-Chirurgical Society in 1918—a lecture so full of matter that it had to be delivered in two parts, with a week's interval. The title was "The Future of the Medical Profession," and the main thesis was that both medical and public opinion had reached the conclusion that medical services must have some kind of State aid and central control, and that for efficient work they needed co-ordinated effort which should be directed from specially equipped institutions. He urged the foundation of a Ministry of Health as the most pressing of current problems.

In the discussions preceding the introduction of the Bill to establish the Ministry it became evident that Sir Bertrand Dawson had a firm grasp of principles and a clear view of the important and even determining share which medicine must take in guiding the Ministry's policy. He was far from being merely a fashionable figure with a gilded name: he revealed himself as a leader of the profession. In his view the Ministry which was in the shaping should be something much bigger than a mere amalgamation of the Local Government Board and the Insurance Commission. The needs of the nation, he declared, required a comprehensive reorganization of the medical services, and such reorganization could succeed only if it enlisted the confidence and support of the medical profession. It must draw to its council, he said, representatives from all departments of medicine, both preventive and curative, and they must have real power.

These declarations he followed up in many addresses, including the presidential address in the Section of State Medicine at the Brussels Congress of the Royal Institute of Public Health in 1920, and also at Divisional meetings of the British Medical Association. It was no uncommon thing to find him at this period attending meetings of Divisions in places like Willesden or Stratford and carrying on the discussions until midnight.

The Consultative Council

The Bill for the establishment of the Ministry of Health went through both Houses of Parliament in 1919. The new Ministry took over all the powers and duties of the Local Government Board and the Insurance Commission, the powers of the Board of Education relating to the health of expectant and nursing mothers, and the powers of the Privy Council under the Midwives Acts. That was the mere clay; into it had to be breathed a living soul.

One of the first acts of the new Ministry, from which much was hoped, was the formation of a Consultative Council on Medical and Allied Services, of which Sir Bertrand Dawson was chairman and Mr. C. J. Bond of Leicester vice-chairman. Among its seventeen members were Dr. J. A. Macdonald, then Chairman of Council of the B.M.A., Sir Robert Bolam, the Chairman-to-be, and Dr. H. Guy Dain, the present Chairman. All the interests—clinical teaching and investigation, private and insurance practice, public health, nursing, dental surgery—were so far as possible represented. Many meetings were held, and eventually, in May, 1920, a scheme for the provision of a chain of health services was elaborated in what was described as an "interim" report, which was published, said Lord Addison, then Minister of Health, "to facilitate discussion of the questions raised in it." The scheme was based on, but a considerable extension of, one proposed by Dr. Middleton Martin, M.O.H. for Gloucestershire. In the roughest outline it was a scheme for basing the domiciliary health services of a district on a primary health centre, a group of these centres being based in turn upon a secondary health centre situated in a town where consultant service and adequate equipment were available, and such secondary centres again in their turn being brought into relation with a teaching hospital. There were many provisions for supplementary services.

The establishment of a Consultative Council and its early report gave rise to high hopes in many quarters. Sir Bertrand Dawson had pleaded that to be a reality such a Council must meet regularly, be empowered to seek information from the heads of Departments, have direct access to the Minister, and have power to initiate advice. The views thus expressed were endorsed by the joint committee of the English Royal Colleges, the British Medical Association, and the Royal Society of Medicine. A leading article in the *British Medical Journal* at the time, while welcoming the Council, begged the profession not to expect from it the impossible, and to realize that it was there to give advice and thereby help to mould sound policy—not there to administer, still less to exercise patronage or promote interests.

The idea that the Council should be a permanent advisory body to the Ministry of Health on medical matters was probably also in the minds of the Government at the time, but it was never carried out. The real achievement of the Council was that it was the first body to focus public opinion on systematized health services. Since then there has been a Royal Commission on National Health Insurance, a Departmental Committee on Scottish Health Services, a Voluntary Hospitals Commission, the report of PEP, the proposals, original and revised, of the British Medical Association for a general medical service for the nation, the interim report of the Medical Planning Commission set up by the B.M.A., and the Government's White Paper. But in 1920 the ideas now familiar, and even stereotyped, were new, and in the hopeful mood of the immediate after-war period everything seemed possible. Certainly there was a Ministry of Health in Whitehall, and there was a Consultative Council even if it was not consulted and even if its report was pigeon-holed; but, better than this, there was a marshalling of ideas on the subject in the medical profession, and an effort to secure that the profession exercised its proper influence in public affairs.

Elevation to the Peerage

Whatever the fate of the Consultative Council, its chairman was by general assent revealed as a medical statesman. He was a consultant, but his long membership of the Council of the British Medical Association, on which he represented the Metropolitan Counties Branch for several years, had familiarized him with the conditions of general practice. He had also a grasp of the problems of medical education. When, therefore, he was created Baron Dawson of Penn universal pleasure was felt. It was not the first time that a medical man had become a peer, but he was the first to be raised to that dignity while still engaged in hospital and private practice and in teaching. His membership of the House of Lords, the roll of which he subscribed on Feb. 18, 1920, ensured that, irrespective of the chances of parliamentary election, there would be one man in the legislative councils well qualified to speak for the profession and in furtherance of national health. At a complimentary dinner given soon afterwards he said that he looked upon the honour paid him as an invitation from the State to the medical profession to take that bigger share in the national life from which it had so far held aloof.

Lord Dawson soon made his personality felt in the House of Lords. In 1926, at the invitation of the Parliamentary Medical Committee, he addressed at the House of Commons a large meeting of members of both Houses on the relations of the medical profession, the General Medical Council, and the public. In 1935 he served on the House of Lords Select Committee which considered the Bill for the registration of osteopaths. There he showed himself a very effective cross-examiner. There are amusing passages in that inquiry, including one in which Lord Dawson encouraged one of the leading exponents of osteopathy to describe how he reconstructed the Eustachian tube by "finger surgery"—placing a finger in the opening of the tube in the post-nasal situation. He also got from two of the chief witnesses on behalf of the osteopaths the admission that in disease after disease drugs were necessary. As the only medical member of the Select Committee it was largely due to his expert and destructive criticism of the claims of these practitioners that the proposals were rejected; but at one point in the inquiry he declared that he began to despair of it. "I have never been mixed up in an inquiry in which it has been so difficult to get an answer."

In 1929 he was made a Privy Councillor, and in 1936, in the only Birthday Honours List of Edward VIII, his personal services to the King's father were fittingly acknowledged by the conferment of a viscounty—the first time this honour has been given to a practising medical man.

Presidentship of the R.C.P.

Lord Dawson became a member of the Royal College of Physicians of London in 1893, and a Fellow ten years later. He was for several years one of its examiners, and he took an active interest in the College administration. Although before 1931 he had not delivered any of its classical orations or lectures, he was in that year elected President, and re-elected until he had served for the unusually long period of seven years.

During his presidency, working in close harmony with the Royal College of Surgeons and also with the recently constituted College of Obstetricians and Gynaecologists, his policy was to foster the influence which these foundations exercise in the domain of State medicine and medical education. He saw to it that the Fellowship of the College became representative of all specialties. He also constantly expressed his desire that the younger Fellows should take a more active part in College affairs; he placed them on various committees and called upon them to take part in the debates in Comitia. He encouraged the co-ordination of individual scholarships so that larger purposes of research might be furthered, as, for example, the succession of grants to investigate different aspects of anaemia or of rheumatoid arthritis. Another task of his was to encourage the participation of the College in large co-operative schemes such as the Curriculum Conference and the British Postgraduate Medical School. "The promotion of public health," he said in an address at the Harveian celebration at the College in 1937, "is something with which in days past this College has been deeply concerned," and he claimed for it at least an equal part in the developments that then seemed to lie just ahead. In a word, under his guidance the College became something more than a dignified academic body: it began to exercise real leadership in the profession.

The British Medical Association

In 1932, when the British Medical Association held its centenary celebrations in London, Lord Dawson was the obvious choice for President. He had been for many years in close touch with the work of the Association, a member of ts Council and of important committees. In 1925 he was chairman of the Marylebone Division, and in the same year at the Annual Meeting at Bath he was President of the Section of Medicine. In all the functions of the centenary week in London and Worcester he gave dignity to what was done, and the innumerable little speeches which the President had to deliver were always gracefully turned. He presided over the Centenary Dinner at the Albert Hall, when the Prince of Wales, afterwards Edward VIII, was the principal guest. No one would have supposed, watching Lord Dawson's spare, active igure during the events of that time, that he was within two years of the allotted span. His presidential address was delivered to a distinguished audience in the Queen's Hall. It was an eloquent survey of medicine—past, present, and future—under the title "One Hundred Years and After." It was marred a little by hurry in delivery, Lord Dawson holding the view that forty minutes was the limit of the patience of any audience. But it reads well. One passage almost at the end may be quoted:

> "The pursuit of knowledge in the medical sciences not only brings esults prolific of benefit to mankind, maybe by adding to life's uality or lightening the burden of suffering, but its very pursuit makes doctors of every nationality and clime into comrades who, animated by the same ideals, think and work together—the gold of endeavour without the alloy of conflict."

In September, 1943, Lord Dawson became our President again by a unanimous vote of the Annual General Meeting, and he was re-elected last year for a further term of office.

Other Interests and Activities

Only a brief reference can be made to the many other activities which occupied Lord Dawson at various times during his busy life. He took a leading part in furthering the Government health and fitness campaign, was a prominent member of the Medical Advisory Committee of the National Fitness Council, and a frequent speaker on this subject at medical and lay gatherings. For many years he was consulting physician to the Ministry of Pensions, the King Edward VII Sanatorium at Midhurst, and the Lambeth (L.C.C.) Hospital Clinic for Heart Surgery. In 1931 he became a member of the Medical Research Council. Among his other interests were the London Provident Hospital Scheme and the People's League of Health, whose campaigns for safe milk and other public health objects he supported.

Lord Dawson's public utterances, to the preparation of which he always gave fastidious care, had a fresh and often a challenging quality. Some of them showed remarkable courage, such as his choice of the Church Congress platform in 1921 to give his views on birth control, then much to the fore in the public mind, and on sex relationships in general. His address, in which he did not hesitate to criticize the Lambeth Conference for its attitude, aroused widespread interest and controversy and was afterwards reprinted as a corrective to the rather misleading press reports published at the time. He held the view, which he expressed many years later at a medical gathering, that changing habits of thought, perhaps involving changes of social habit, do not necessarily indicate, as many religious people are inclined to suppose, a deterioration of the race. He was himself a loyal Churchman, but he wanted the Church of England to be more liberal in spirit.

In 1922–3 he was President of the Medical Society of London, and in his presidential address, which covered many subjects, he touched on psycho-analysis, a subject then relatively unfamiliar even to many in the medical profession. His criticism was not so much of its conception as of the method of its presentation and handling. A subject on which he often spoke was professional secrecy. In an address to the Medico-Legal Society many years ago he declared that public opinion was emphatically in favour of some measure of privilege for the doctor, though he admitted that when once the principle of such privilege had been conceded the difficulties of definition would be very great. On the questions raised by the Bourne trial in 1938, which turned upon the right of a medical man to bring about an abortion in the case of a young girl pregnant as the result of rape, Lord Dawson had very decided views, which he expounded at the annual dinner of the Medico-Legal Society in the presence of the judge who had presided at the trial.

Lord Dawson was honoured by many universities and other bodies both at home and abroad. In 1925 he received the Sc.D. of the University of Pennsylvania, and, on the same American visit, the LL.D. of McGill. In 1926 the D.C.L. of Oxford was conferred upon him, and in 1927, on the occasion of the Annual Meeting of the British Medical Association, the LL.D. of Edinburgh. The Royal College of Surgeons of England elected him an Honorary Fellow in 1932.

He married, in 1900, the daughter of Sir Alfred Yarrow, founder of the great shipbuilding business at Glasgow. The help which Lady Dawson gave to him during their long married life was often publicly acknowledged. During his first presidency of the British Medical Association, when some compliment was paid to her, he said that "if any of us honestly looks back on his career he will find it difficult to estimate what a large part of his success is due to his wife, and how little he could have achieved without her. . . . We cannot be too grateful for the gentle autocracy under which we live." Lord and Lady Dawson had three daughters. Their country home was for many years Dell Cottage at Penn, from which Buckinghamshire village he took his title.

Dr. H. GUY DAIN, Chairman of Council, writes:

The British Medical Association mourns the loss of its so distinguished President, Lord Dawson of Penn. Rarely are the qualities of a sound physician and a great statesman to be found in the same person. These qualities, displayed in Lord Dawson, were combined with a gentleness of spirit and a kindness of heart which made him a great gentleman. He took the keenest interest in the development of medicine and of medical services, and his breadth of vision and statesmanship did much to advance both. Typical of his devotion to our profession was his acceptance of the Presidency of the British Medical Association two years ago, at a time when he might properly be passing responsibility to others. This he did because he felt he should place his help and experience at our service in these critical days. By his death not only the Association but the whole profession loses its acknowledged leader.

Sir ARTHUR S. MACNALTY writes:

It is difficult to realize that Lord Dawson is dead. With his erect figure, his quick step, and his energetic speech he seemed the embodiment of eternal youth. He resembled Cicero in liking young men; he helped and encouraged them in their careers and readily became young with them. Many a physician of to-day owes his first steps on the ladder of success to the helping hand Lord Dawson extended to him. In my own case, when I was a candidate for the medical registrarship at the London Hospital, he invited me to a dinner-party of leaders of the medical profession at his own house in order to tell me that I had secured the appointment. Young men appreciate such rare consideration. At the London Hospital he gave me charge of his beds sometimes when he was absent, and often asked me to see interesting cases with him. He delighted in discussing new advances in medicine. In the last war he offered to take me to France with him, but the War Office and the Local Government Board would not release me from work in connexion with epidemics and inspections of camps and hospitals in this country.

Lord Dawson had the mind of a statesman. Not only did he maintain and advance the interests of the medical profession as President of the Royal College of Physicians, President of the British Medical Association, and acting chairman of the governing body of the British Postgraduate Medical School, but he worked incessantly for national health and the improvement of social conditions. He was in the councils of the Ministry of Health from its inception. The Interim Report of the Consultative Council for Medical and Allied Services, of which he was chairman, reveals his far-seeing and able gifts. This plan is the parent of all regional schemes of health services. It represented an honest and wise attempt to reconcile conflicting medical interests for the benefit of the public. It is regrettable that medical and public opinion were not at the time sufficiently enlightened to give adequate consideration to this report. We are still labouring at the problem which he would have helped to solve in 1920.

When I became Chief Medical Officer of the Ministry of Health he helped me in countless ways throughout my tenure of office. He was a member of the Medical Advisory Committee to the Minister, where his advice was of the utmost value, and we had the benefit of his knowledge of men and affairs in dealing with many health problems. His high standards of public duty and service persisted to the end. He told me last year that he was tired, but nevertheless felt that he must not refuse the invitation to be President of the British Medical Association at this critical time. He had a keen sense of humour, which often stood him in good stead. Once, when I expressed the hope that he was writing his reminiscences, he said: "Oh, no! I would have to leave the best things out. I could never dare to tell them." He was essentially human, a leading and vivid figure in British medicine. "He walked with Kings nor lost the common touch."

Dr. HENRY ROBINSON writes:

May one who, as a general practitioner, many times met Lord Dawson in consultation testify briefly to his clinical wisdom and not less to his tact and sympathetic handling of sick people and their relatives? Apart from his great gifts as a physician, I have known his diagnosis (on a surgical case) to be right when that of one of his surgical colleagues was wrong; and I have known him furnish a most excellent opinion on a gynaecological case, once at least. But he impressed me most, perhaps, some thirty or more years ago when I called him to see an old gentleman of 78 years who had survived an old-fashioned lobar pneumonia first of the right lung and then of the left. Thereafter he started to have daily rigors with pyrexia up to 105°, and I withdrew two or three ounces of turbid fluid from his left pleural sac; this was reported to contain virulent streptococci. It was at this stage that Sir Bertrand Dawson, as he then was, came to my help. I remember well how he sat on the edge of the bath (for the bathroom was the only place where we could confer privately) swinging his legs off the ground, and saying in that extremely pleasing voice of his: "I don't know why, but I have a feeling that this man is going to recover. I agree that to operate on him would be just to kill him; I advise you to trust to Nature, and I think he will get well." And get well the old gentleman did, dying of old age several years later.

We regret to announce the death on Feb. 24 of FRANCIS JOHN GREEVES, J.P., L.R.C.P., L.R.C.S.I., at Larkhill, Blackburn. Born in Galway in 1870, he received his medical education in Dublin, qualifying in 1892 and winning the silver medals in medicine and surgery. After a period as resident at Jervis Street Hospital he came to England, and in 1895 took over the practice of Dr. Bastable at Larkhill, where he lived and practised all his life. His activities were many and varied, both medical and social. He took a lively interest in medical politics, and on the formation of the Insurance Committee was elected as representative of the practitioners, remaining a member until his death. He was chairman of the Local Medical and Panel Committee from its inception, and for many years its representative at the Panel Conferences; he also served as chairman of the Blackburn Division of the B.M.A. during the last war. Dr. Greeves took an active interest in local politics, and was elected to the Blackburn Town Council in 1900. He was soon chosen chairman of the Public Health Committee, and held the position for twenty years. In 1906 he became a borough magistrate and in 1912 a barrister of Gray's Inn. He was the first chairman of the Maternity and Child Welfare Committee. In 1903 he was made a member of the Library Committee, in 1915 vice-chairman, and in 1927 chairman. His colleagues showed their appreciation of his services when his portrait in oils was unveiled in the Art Gallery in 1935—King George's Jubilee. In 1922 he was elected an alderman and became mayor of the borough in 1938—a singularly popular election. In spite of a crowded and many-sided life Dr. Greeves had a number of hobbies, included in which were a love of music, drama, art, and reading. His record of service is most impressive. He was respected and loved by all—a truly good and great man.—F. W. T.

Dr. BENJAMIN ARTHUR RICHMOND died on Feb. 26, in his 75th year, at Trefriw, Caenarvonshire. He had a distinguished student career at Guy's, taking the B.Sc.Lond. with honours, and the gold medal in the M.D. examination. Dr. Alfred Salter, a fellow student, had begun practice in Bermondsey with the intention of giving what was a medically neglected area a good medical service, and Richmond joined him, and the practice quickly grew to one of six partners. The status of these partners may be gauged by the fact that Dr. Salter has long been M.P. for the Division, and both he and Richmond were made J.P.s of the County of London. Richmond took a very active part in the National Health Insurance struggle and became the first whole-time secretary of the London Panel Committee in 1916. In 1920 he was appointed Regional Medical Officer to the Ministry of Health and served successively in the South-Eastern area and in Birmingham. Dr. Richmond joined the B.M.A. in 1912, resigned when he was appointed to the Ministry, but re-joined in 1925. He served on the Executive Committees of the Camberwell and the Woolwich and Lewisham Divisions of the B.M.A.

Dr. EDWARD MCCULLOCH died in Plymouth at the age of 68 on March 4. Graduating M.B., Ch.B. of Edinburgh University in 1898 he came to Devonport as house-surgeon at the Royal Albert Hospital; subsequently he entered general practice and continued as hon. radiologist to the hospital. He was keenly interested in medical and social politics, being a member of both the Panel and Insurance Committees from their inception. He took an active part in the formation of the Protection of Practices Scheme and the Local Medical War Committee, acting as hon. secretary. He was also acting hon. secretary of the Plymouth Division, B.M.A. Both of these onerous positions he had to relinquish when in the spring of 1941 he sustained injuries during an air raid in which his house was demolished. He never completely recovered from the effects of this accident. Dr. McCulloch was a past president of the Plymouth Medical Society and in the last war he was consulting radiologist to the E.E.F. His death is deeply regretted by his colleagues, who extend their sincere sympathy to his widow and two daughters.—G. D.

The following well-known medical men have died abroad: Dr. MAURICE LAMM BLATT, professor of paediatrics at the University of Illinois College of Medicine, aged 65; Dr. CHARLES LANGDON GIBSON, emeritus professor of surgery at Cornell University Medical College, aged 80.

Medical Notes in Parliament

The Flour in the Loaf

Lord Teviot in the House of Lords on Feb. 28 asked why the extraction rate of wheat had been reduced below the standard of 1942. He moved that this standard should be regarded as the minimum compatible with the health of the people and should be restored. He recalled that before the war the extraction had been 70 to 72% and that in March, 1942, it had been raised from 75% to 85%. Were the millers going back to the pre-war extraction? All medical and scientific authorities were anxious at the reduction from 85%. Had the Ministry of Health, the Special Diets Committee of the Medical Research Council, and the Scientific Advisory Committee on Food Policy, set up by the Ministry of Health in 1940, been consulted? Lord Horder was the medical adviser of the Ministry of Food. Had he been consulted? It had been found that wholemeal or high-extraction flours were of more nutritive value when tested on animals than 70% extraction flour, even when that was fortified by the addition of food factors removed in the milling of white flour. There were eleven such factors, but it had only been possible to manufacture three of them to fortify the white loaf. There were also unidentified factors and trace elements. It was ridiculous o claim that the addition of three factors would make white flour as nutritious as 85% flour. He disputed the assertion hat Dublin experience showed that high-percentage extraction flour caused rickets. There had been no records of the ncidence of rickets in Irish cities before the period in question. Cod-liver oil and halibut-liver oil had been unobtainable in Eire when high-extraction flour was in use. Dr. Sanders, medical officer for Cork, had pointed that out. Tests by the Medical Research Council had shown that the maximum nutriive value of wheat with the minimum of bran was secured by 85% extraction. White bread of 70% extraction enabled a person to take in daily 150 to 200 international units of vitamin B. Each person should take in 600 units daily. Our ancestors, eating wholemeal bread, took in about 900 to 1,000 units per diem. The plea was advanced that the wheat offals were wanted to produce more milk, but farmers did not give heir cows wheat offals.

Lord Addison said it was exceedingly profitable to the millers to increase the percentage of offals taken out of the wheat. White flour nearly composed of starch would absorb more water and the number of loaves produced from a quarter sack of flour could be raised from 92 or 96 to 102. The addition was water, charged at 2d. a lb.

Lord Horder pointed out that Lord Woolton, before raising he extraction rate by 10%, had received assurances that he was not compelling the people to eat a bread which was not digestible. In giving those assurances Lord Horder and cerain of his colleagues bore in mind the disturbed digestion of patients suffering from ulceration of the stomach or the bowels. Prof. Davidson and his colleagues in Edinburgh confirmed that assurance. Some cases of ulceration of the stomach healed more quickly under the national wheat-meal bread. That was not surprising, seeing that the healing of ulcers of that type was aided by a rise in the general nutrition of the patient. The same experience was seen in the feeding of infants, and he Minister of Food therefore stopped, 18 months ago, the allocation of white flour for the manufacture of infants' food. No complaints followed the action. On March 11, 1942, he had said that no other step which the Government could take was so calculated as this to raise the level of nutrition. That orecast, after three years' experience, proved correct. If the atisfactory health of the country was not mainly due to this, hen doctors did not know to what it was due. Deficiency diseases did not really exist in this country. An American authority came here to study deficiency diseases in the third and fourth years of the war, but found no clinical material. Anaemia had greatly decreased in incidence. A more general effect of the national wholemeal bread was that the country was less constipated, and the harmful habit of swallowing purgative drugs had been reduced. Facts like these had become general knowledge. Therefore people asked why the extraction rate had been reduced. Prof. Kay, of the National Instiute for Research in Dairying, declared that the vitamins of wheat offals were wasted on the cows. Recent researches at he Cereals Research Station at St. Albans had given new knowledge of the intimate composition of the wheat grain. This research would affect the technique of milling, but the Government had been too hasty in "cashing in" by lowering he extraction rate by 2½% in October, with a second 2½% eduction in January.

Lord Geddes said it paid the miller to have people eating white bread because they had to eat so much more to get the feeling of nutrition which they had from eating brown bread. Every medical man would agree that 85% extraction had made for health and for resistance to disease.

Lord Hankey said the Government had been warned for years by their own experts, by the Medical Research Council, and by international experts that ordinary white bread was extremely deficient in nutritional content. Successive Governments neglected that warning and brought the nation to the first stages of degeneracy. Advertisements in newspapers of proprietary medicine, and especially of aperients, fell away after the change in the extraction of flour was made in 1942. Now a powerful move toward what Sir Edward Mellanby had called "the meretricious attractions of the old white bread" was being made even before the shipping situation had eased. He asked whether experts had been consulted; it was evident that Lord Horder was not.

Lord Horder, replying to an intervention by Lord Woolton, said he was a member of the Nutrition Committee of the Ministry of Health and the Ministry of Food. Lord Hankey asked whether that joint committee had been consulted, or the Chief Medical Officer of the Ministry of Health, or the Medical Research Council, or the Scientific Adviser to the Ministry of Food, or the Scientific Advisory Committee. If they were consulted, did they consider the new policy provided the best bread in the interests of public health? Lord Bledisloe said millers produced what the public demanded. He suggested an experiment between three adjoining villages—one fed on bread of the 72% extraction flour which prevailed before the war, one on bread of 80% extraction, and one on bread of 85% extraction.

Lord Woolton Explains

Lord Woolton said that the Minister of Health had been consulted. The Chief Medical Adviser to the Ministry of Health and the Scientific Adviser to the Ministry of Food had been consulted. The Secretary of the Medical Research Council had been brought into the discussion. So far as Lord Woolton knew there had been no consultation of the Scientific Advisory Committee nor of the Special Diets Committee of the Medical Research Council. That last committee was set up to advise on food requirements of persons suffering from specific diseases, so there was no point in calling them into consultation on this issue. The millers had also not been consulted. It was not proper to ask a Minister what had been the advice of this or that adviser. Therefore he did not answer the question. Ministers must not shelter behind the advice they received. The decision had been taken when he was still Minister of Food. He took it on seeing a demonstration at St. Albans that, by separating the scutellum of the wheat germ and bringing it into the flour, the same amount of vitamin B could be secured with a lower rate of extraction. This was tried on a commercial scale, and it was shown that the resulting flour was as rich in vitamin B as before, save for 0.08%, but with less bran left in the flour. Bran was not good for the human stomach. The opinion of the scientific people who had been his advisers during the war was that the reduction could safely be made to 82½%. Since then it had been suggested that the Government could go lower. It was trying that experiment out. The Government wished to preserve the quality of the flour, not a percentage of extraction rate. He would give an undertaking that it would preserve the quality of the flour. He believed that as a result of war experience the country would demand high-quality bread.

The Earl of Portsmouth said he was not prepared to say the removal of bran from bread was good. Constipation was the national curse, and he noticed that "bemax," which was almost unobtainable two years ago, was coming on the market again. This product was largely the result of removing the most valuable constituents from the wheat berry before it was made into white bread. These were then sold as a tonic at about 100 times the price they would have cost if left in the loaf. Lord Balfour of Burleigh feared that in the reduction from 82½% to 80% there was lost an undue proportion of the iron. Since the change was first made to high extraction there had been a remarkable improvement in health. The common factor was that everyone ate bread, which was presumption that bread was a predisposing cause of the improvement. There had been a striking decrease in deaths of infants under 1 month, a great reduction in deaths due to appendicitis, a reduction in deaths due to inflammation of the gallbladder, a great reduction in deaths due to exophthalmic goitre, a reduction in diabetes mellitus, an enormous improvement in the death rate of children aged 5, and a substantial decrease in mortality associated with pregnancy. There was evidence of a diminished amount of anaemia.

Lord TEVIOT asked for an assurance that the present extraction was not below 80%. Lord CRANBORNE replied that if imported flour was added the mixture might be below 80%, but not in any other case. Lord TEVIOT said he was far from happy at the position, but he withdrew his motion.

Committee on Homeless Children

The terms of reference of the Committee on the Care of Homeless Children, the members of which were announced in these columns on March 10 (p. 351), are as follows:

"To inquire into existing methods of providing for children who from loss of parents or from any cause whatever are deprived of a normal home life with their own parents or relatives; and to consider what further measures should be taken to ensure that these children are brought up under conditions best calculated to compensate them for the lack of parental care."

Doctors in the Army

Sir JAMES GRIGG said on Feb. 27 that the shortage of doctors, and especially of surgical specialists, was so acute in the Army that it was usually impossible to release any unless replacements were immediately available.

Achievements of British Science in War

Mr. SALT asked on March 1, in view of the fact that no reports had been issued by the Medical or Agricultural Research Councils for the past five years, what steps were being taken to issue reports as soon as possible dealing with such of their activities during the war as could be published without security objection. Mr. ATTLEE replied that it had been necessary, owing to war conditions, to suspend publication of reports not of direct importance to the war effort, including these annual reports. A large number of notable reports had been issued by these bodies during the war. Other reports would be published as soon as security and other considerations permitted. The form of such publication was now being reviewed.

In a previous reply Mr. Attlee told Mr. Salt that an archivist had been appointed to prepare for publication records of the achievements of British science during the war.

Research by Water Undertakings

On March 6 Mr. PRICE asked the Minister of Health what was the present estimated expenditure on scientific research by water undertakings in Great Britain; whether they made any contribution to the Water Pollution Research Laboratory; what research stations of their own were maintained; and whether he anticipated that such research work would be increased under the provisions of the Water Bill now before the House. Mr. WILLINK said that he had no detailed information on the subject of the first part of the question; the answer to the second part was "No." With regard to the third part, a number of the larger undertakings had laboratories where they carried out experiments in connexion with local water supply difficulties, the cost of which was included in the general expenses of carrying on the undertaking. As to the last part of the question, section 77 of the Third Schedule of the Water Bill would, when applied to a water company, enable it to make contributions for furthering research where it had not that power at present.

Scottish Hospital Patients Treated under E.M.S.

On March 6 Mr. HUBBARD asked the Secretary of State for Scotland how many cases had now been transferred from the list of Scottish voluntary hospitals and treated under the Emergency Hospital Scheme; and what were the financial arrangements with the voluntary hospitals for treatment of such cases.

Mr. JOHNSTON: Under a scheme which I arranged with the Scottish Branch of the British Hospitals Association in January, 1943, 32,250 patients from the waiting lists of voluntary hospitals in Scotland have been treated in Emergency Hospitals set up by the Department of Health for Scotland. For this service an overall charge of 30s. per case, irrespective of the length of stay, is made against the voluntary hospital. The scheme has had a considerable effect in reducing the waiting lists and has been of immense benefit to thousands of patients.

Sick Persons in Channel Islands.—In answer to Capt. Gammons on March 1 Mr. HERBERT MORRISON said it was not the policy of the Government to evacuate any of the able-bodied civilian population of the Channel Islands. Negotiations were in progress through the International Red Cross Committee for the evacuation of sick persons who could not be given in the islands the medical attention which their condition demanded. It was contemplated that a neutral medical commission should proceed to the islands, as soon as the necessary arrangements had been made, for the purpose of selecting those persons whose removal was imperative on medical grounds

Medical Services in Jamaica.—Mr. RILEY on Feb. 28 suggested that Col. Stanley should investigate the dissatisfaction in Jamaica with the Government's medical services. He said at least three medical officers had resigned from the service during the past year from dissatisfaction with its administration. Col. STANLEY said that while in Jamaica he had received representatives of the local branch of the British Medical Association, who expressed dissatisfaction on some points affecting the medical service. He had informed them that such matters were now the concern of the new Executive Council and Legislature in Jamaica. He was therefore not prepared to intervene on the question of an inquiry into the causes of any recent resignations from the medical service.

Notes in Brief

Legislation to amend the Housing (Rural Workers) Acts is to be introduced shortly, and in any case before the end of the session.

Double summer time will begin on April 2 and continue till July 15. It is hoped that no extension will be necessary before that date, and that it may be possible to revert to Greenwich mean time on Oct. 7.

Col. Stanley has approved in principle proposals from the Governor of the Seychelles for a reorganization of the Colony's health services and improvements to the hospital.

Sir James Grigg stated on Feb. 28 that efforts had been made to establish in camps in Germany for prisoners of war substantial reserves of medical supplies and comforts, in preparation for the mass movement of prisoners from the perimeter toward the central districts.

Medical News

The Harveian Society of London announces that the Director General of the Army Medical Services, Sir Alexander Hood, K.C.B. will deliver the Harveian Lecture on "Total Medicine" at the Royal College of Surgeons of England (Lincoln's Inn Fields, W.C. on Monday, May 28, at 3.30 p.m.

The annual meeting of the Association of Surgeons of Grea Britain and Ireland (45, Lincoln's Inn Fields, W.C.2) will be held at the Royal College of Surgeons of England, Lincoln's Inn Fields W.C., on Wednesday and Thursday, May 2 and 3. The provisiona programme is as follows: May 2, morning, business meeting and discussion on "The Education of the Surgeon," to be opened by Prof. Ernest Finch, Prof. J. R. Learmonth, Prof. John Kirk, Prof W. G. Barnard, and Major-Gen. W. H. Ogilvie; afternoon, shor papers; evening, annual dinner at the Connaught Rooms. May 3 morning, discussion on "Carcinoma of the Recto-sigmoid," to be opened by Mr. R. Scott Mason, Dr. Cuthbert Dukes, and Mr. O. V Lloyd-Davies; afternoon, operating sessions. A full programme wil be issued in April.

There is a great deal of concern about the proposed closing down of the wartime nurseries. In response to requests from mothers al over London, the London Women's Parliament (24, High Holborn W.C.1) is calling a conference on "Nurseries—A Social Service" at B.M.A. House, Tavistock Square, on Sunday, March 18, at 3 p.m At the conference women for whom nursery provision has become a necessity will be able to express their views. With nursery staffs trade unionists, borough councillors, welfare workers, and representatives from women's organizations they will work out a plan o action to ensure the continuation of nurseries after the war. Th speakers will include a medical officer of health, a matron supervisor of nurseries, and a mother.

At a meeting of the Medico-Legal Society at 26, Portland Place W., on Thursday, March 22, at 5 p.m., Mr. Donald C. Norris wil read a paper on "Medico-Legal Examinations and Reports."

The sixty-fifth annual meeting of the Mental After-Care Association will be held at Burlington House, Piccadilly, W., on Friday March 23, at 2.45 p.m. under the presidency of H.R.H. Princes Arthur of Connaught. Col. Y. Kneeland, U.S. Army, Brig. G. W. F James, M.D., and Col. Henry Yellowlees, M.D., chairman of th association, will speak. All interested are invited to attend.

A meeting of the Clinical Society of the Royal Eye Hospital wi be held at the hospital, St. George's Circus, Southwark, S.E.1, o Friday, March 23, at 5 p.m., when a talk will be given by Mr. P. M Moffatt, F.R.C.S., entitled "A Critical Survey of Orthoptics."

A meeting of the Medical Society for the Study of Venerea Diseases will be held at 11, Chandos Street, W., on Saturday March 24, at 2.30 p.m., when Surg. Capt. T. R. Lloyd-Jones, R.N and Surg. Cmdr. F. G. Maitland, R.N., will open a discussion o "Early Syphilitic Infection treated with Arsenotherapy an Penicillin."

Mr. W. K. Fitch, editor of the *Pharmaceutical Journal,* will giv a lecture on "Pharmacists with the B.L.A." before the Pharmaceutical Society of Great Britain, 17, Bloomsbury Square, W.C., o Tuesday, March 20, at 7 p.m.

The following films will be shown by the Scientific Film Association at the Royal Society of Medicine, 1, Wimpole Street, W., on Wednesday, March 28, at 5.30 p.m., and again at 8 p.m.: "The Nose Has It"; "The Action of Cilia and the Effect of Drugs on their Activity"; "Open Drop Ether"; "Unwanted Guests"; and "Conquest of a Germ." Admission by ticket only, and those who have not already done so should apply immediately to the honorary secretary of the medical committee, Dr. S. J. Reynolds, 14, Hopton Road, London, S.W.16.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* measles notifications were 4,049 higher than last week, and those for dysentery 36 higher. The total for scarlet fever rose by 47 cases, and for diphtheria by 30—Lancashire reporting a rise of 36. The incidence of acute pneumonia fell by 88 cases.

The notifications of dysentery were the largest for twenty-four weeks. The only fresh outbreaks of any size were in Sussex, East Grinstead U.D. 20, and Berkshire, Maidenhead M.B. 13. The largest of the other returns were in Lancashire 38, London 34, Essex 25, Surrey 24, Yorks West Riding 21, Devonshire 19, Glamorganshire 15, Gloucestershire 14, Middlesex 11.

In *Scotland* measles notifications rose by 32 cases, and scarlet fever by 31, but there were 38 fewer cases of acute primary pneumonia. Seven more cases of diphtheria were recorded than last week, two-fifths of the total being notified in Glasgow. Cases of dysentery were 5 fewer than in the previous week; the largest returns for this disease were in Falkirk 37, Edinburgh 31, Glasgow 22, Stirling County 11, Renfrew County 10.

In *Eire* there was a general increase in infectious diseases, the totals being higher than last week by the following amounts: measles 34, whooping-cough 19, scarlet fever 14, diarrhoea and enteritis 14, diphtheria 13. Measles and whooping-cough were practically confined to two areas—Wexford, New Ross R.D., with 25 and 37 cases respectively, and Dublin C.B. with 13 and 28 cases.

In *Northern Ireland* the incidence of measles continued to fall, and the lowest total for nineteen weeks was recorded.

The Measles Epidemic

The notifications of measles in England and Wales, 23,216, reached the highest level since the outbreak of the war, when this disease was first made notifiable. The largest returns in the two preceding outbreaks were 20,146 in the eighth week of 1943 and 17,853 in the first week of 1941. Although the incidence is now 22 times the minimum of last summer, the present level is not officially regarded as having reached epidemic proportions. From an academic point of view it is perhaps difficult to decide what level of incidence constitutes an epidemic, because the returns are available for five years only, and the normal limits of the biennial rise are unknown. But notifications 20 times higher than the endemic level seem to justify the description "epidemic," whether such totals occur periodically or spasmodically. In the present outbreak the rate of increase has been greater than in the preceding ones. The notifications in eight-week periods are:

Weeks	1944-5	1942-3	1940-1
45 to 52	61.894	91,710	111,614
1 to 8	126,970	122,369	128,705

The regional distribution varies from that of the previous epidemic, the incidence being lower in the south and higher in the north. The notifications in London, 977, are only two-thirds of the maximum weekly total for 1943, but Yorkshire's total of 4,961 cases is considerably above the previous maximum. Deaths in the great towns during the first eight weeks of this year numbered 122, compared with 4, 155, 15, 178, for the corresponding periods of the four preceding years. The largest rises in notifications during the week reviewed were: Yorks West Riding 586, Staffordshire 410, Middlesex 394, London 337, Durham 324, Essex 304.

Typhus in Cologne

Typhus had appeared in Cologne before the Allied occupation. The German authorities estimate that there are over 200 cases scattered throughout the city.

Week Ending March 3

The notifications of infectious diseases during the week in England and Wales included: scarlet fever 1,461, whooping-cough 1,462, diphtheria 470, measles 22,480, acute pneumonia 905, cerebrospinal fever 77, dysentery 399, paratyphoid 3, typhoid 13.

No. 8

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 24.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

Stillbirths	192	17	27			222	17	28		
Rate per 1,000 total births (including stillborn)			32					33		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Hysterorrhaphy

Q.—*I did an abdominal operation for dystocia. When the abdomen was opened the foetus was found lying free in the peritoneal cavity, the uterus had ruptured, and the placenta was still in the uterus. The infant was delivered out of the abdominal wound, the placenta was expressed, and the rent in the uterus repaired. The patient is quite fit to this day, and the baby is still alive and is 2 years old. Is this operation a Caesarean section or hysterorrhaphy?*

A.—Hysterorrhaphy is perhaps the best term to be employed for the particular operation. The case is of great interest clinically, because there is an implication that the ruptured uterus had not been diagnosed. The literature on the subject shows that it is not uncommon to find an unsuspected rupture of the uterus after the abdomen has been opened.

Diphtheria Immunization after Serous Encephalitis

Q.—*My boy of 13 suffered when he was 9 from an acute serous encephalitis which developed spontaneously. It began with a rash and he developed gastro-intestinal disturbance, delirium, and convulsions. For one or two days he had a slight paresis of one hand. The C.S.F. showed 15 cells per c.mm. He made a quick and complete recovery. Is there any danger connected with an immunization against diphtheria?*

A.—The illness "serous encephalitis" from which this boy suffered four years ago may have been due to one or other of several conditions. It could have been post-infectious encephalitis such as happens after measles, mumps, or vaccinia, but there is no history of any such antecedent infection; it might have been a mild attack of polio-encephalitis (did it occur in the late summer, or was there poliomyelitis in the district?); or, with the history of an accompanying rash, it might have been a meningococcal septicaemia with some cerebral localization; or it may have been an acute allergic condition, but to what? In any event, the advisability of immunization against diphtheria is the point now in question, and in this connexion an antecedent history of encephalitis of whatever aetiology is no bar to the performance of the Schick test, which in a boy of this age is an essential preliminary to artificial immunization. If the Schick test is positive and there is no pseudo-reaction with the control material, it is safe to go ahead with immunization—either two doses (0.2 and 0.5 c.cm.) of A.P.T. at one month's interval or three doses of 1.0 c.cm. each of T.A.F. at 2- and 3-week intervals.

B.S.R. Estimation by Westergren Tubes

Q.—*What is the technique of the B.S.R. estimation by means of Westergren tubes?*

A.—Westergren's apparatus and tubes may be bought from any firm dealing with laboratory supplies. 0.4 c.cm. of a sterile 3.8% solution of sodium citrate is drawn up into a 2-c.cm. syringe, the needle of which is then introduced into a vein and the syringe filled with blood to the 2.0 c.cm. mark. The mixture of blood and citrate is emptied into a specimen tube, mixed well, and then drawn up as soon as possible in the special Westergren tube to the zero mark. With the finger on the top of the tube, the point of the tube is firmly placed on the rubber disk at the base of the Westergren stand, and the top of the tube slid under the spring clip. The blood must be examined within 3 hours of collection. The number of millimetres of clear plasma at the end of 1 hour is the sedimentation rate. The normal values are: for men 2-5 mm., and for women 3-7 mm. Sometimes a second reading is made after a further hour. The normal values for this 2-hour reading are: for men 7-15 mm., and for women 12-17 mm. It is essential that the Westergren stand be absolutely vertical, as slight variation from the vertical may cause considerable increases in the sedimentation rate. Many Westergren stands are made of wood and are liable to warp, so this point must be watched.

Body Odour

Q.—*A girl aged 12 has had to leave school on account of complaints by other boarders of a disagreeable smell emanating from her—this also being noticed by her parents. She has not menstruated yet. I could find no cause for the complaint in urine, etc. Can you suggest treatment? Scents have been tried without success.*

A.—In such a case it is necessary to exclude infection of the antra and upper air passages, gingivitis, bronchiectasis, vaginal discharge, and diurnal enuresis. An unsuspected fat dyspepsia occasionally causes halitosis, and the symptom is relieved by restricting the fat in the diet. Investigation may fail to reveal any organic lesion, in which case the following simple remedies should be given a trial. If the smell is coming from the breath creosote capsules should be prescribed; if from the skin, she should be bathed twice a day and have a simple deodorant applied to the axillae and groins. In addition she should wear only clothes which can be regularly washed, and these should be changed twice a week. The hair should also be washed frequently. The possibility that the child is deliberately sucking some unpleasant-smelling tablets should be considered.

Penicillin Administration

Q.—*In an attempt to overcome some of the difficulties of penicillin treatment (painful injection, rapid absorption and excretion, destruction by gastric juice) would any of the following methods of administration be likely to be efficient: (1) frequent inunction of a penicillin ointment with a lanoline or preferably eucerine base, (2) sublingual medication, (3) inhalation for certain diseases of the respiratory tract, (4) suppositories for anal affections?*

A.—These are ingenious suggestions, and although there are objections to them their usefulness could be determined only by trial. The first two are presumably intended as substitutes for intramuscular injection when systemic treatment is required. Whatever the route of administration, the rate of renal excretion demands that the total daily dose absorbed should be not less than 100,000 units. Little is known about the absorption of penicillin by the normal skin: unless this were unexpectedly free and rapid the disturbance to the patient at night by repeated vigorous inunction over a wide area might be greater than that caused by injections. Penicillin is absorbed from the mouth, but part of the dose so administered would be swallowed and destroyed in the stomach; this must therefore be a wasteful method. Of the two forms of local treatment suggested, inhalation, if frequently repeated, is theoretically sound and well worthy of trial. Rectal medication is unpromising for two reasons: that intestinal bacteria destroy penicillin, and that most intestinal infections are due to insensitive organisms. Apart from female gonorrhoea (which should be treated systemically) what infection in this area is there which could benefit?

Multiple Telangiectases

Q.—*A patient has multiple telangiectases of the face and nasal mucosa, resulting in alarming attacks of epistaxis of an arterial type. They are extremely difficult to arrest, and treatment has caused considerable destruction of the nasal septum and inferior turbinates. Any suggestions?*

A.—The usual methods of treatment of telangiectases are by electrolysis, ignipuncture by galvanic or diathermic cautery, radiotherapy, or by carbon-dioxide snow. Of these, electrolysis would seem to be the method of choice in this case. The questioner does not state what treatment has already been tried. The destruction of tissue must have been due either to pressure from plugging or to sloughing from sepsis. Further loss of tissue ought to be prevented by the local use of penicillin (if available), which should keep the part free from septic organisms. It could be applied in the form of a powder, which could be insufflated.

Menstruation and Epilepsy

Q.—*Is there any knowledge of the result of artificial induction of the menopause by x rays in the case of epilepsy occurring only at the menstrual period?*

A.—I have no personal knowledge of this having been done, nor do I know of any reference to it in the literature. It is by no means certain that the fits would stop, for although epilepsy often responds to highly specific precipitating causes such as menstruation, as in this case, removal of the precipitant only removes the immediate cause. The patient would still be a potential epileptic.

Leukonychia

Q.—*What is the cause of leukonychia, and is there any reasonably certain cure for the complaint?*

A.—Leukonychia may be limited to small white spots or transverse bands, or may affect the whole nail substance. It has been explained by "soft" areas which shrink and admit air, or more probably by defect of normal keratinization from injury or malnutrition. It is doubtful if the condition can be improved by treatment. Simple cosmetic applications disguise but do not cure.

Hyoscine Hydrobromide

Q.—*In view of the partial but undoubted success of hyoscine hydrobromide in the cure and prevention of sea-sickness, do you think it could be used with good effect for pregnancy sickness?*

A.—Hyoscine is effective for sea-sickness only when relatively large doses are used, and even then it is effective only in certain individuals. Holling, McArdle, and Trotter (*Lancet*, 1944, 1, 127) found that sea-sickness was more efficiently prevented by hyoscine than by any other drugs they tried. They noted no unpleasant side-effects except dryness of the mouth, and no effect on vision, on ability to shoot, or on capacity for physical exertion. But they point out that their experiments were performed on young, fit men and for short trips only—that is, the drug was not given by repeated administration over a number of days. The doses used were 0.6 mg. (1/100 grain) and 1.2 mg., the latter being more effective. It is doubtful whether hyoscine would be of any value in controlling pregnancy sickness, and the procedure would not be without danger, especially if the large doses mentioned were needed. Hyoscine is a powerful deliriant, and in some patients causes uncontrollable excitement. With repeated administration unpleasant side-effects such as dryness of the mouth and disturbances of vision might result. In pregnancy sickness hypnotic drugs are best avoided, though a mild sedative such as potassium bromide may be given to ensure sleep. Patients are best treated along general lines, including avoidance of dehydration, high carbohydrate diet, and the administration of vitamin B. In severe cases admission to hospital is advisable.

Ménière's Syndrome

Q.—*Could you suggest any treatment that will make the attacks of Ménière's syndrome few and far between?*

A.—The attacks of Ménière's syndrome are thought to be due to faulty water metabolism, producing a "waterlogged" condition of the inner ear. Treatment is to avoid the ingestion of sodium salts. The use of table salt at meals is forbidden, some substitute taking its place. The daily fluid intake is also drastically reduced. If such measures fail, the offending labyrinth may be destroyed by injecting alcohol into the external semicircular canal. This is permissible only when hearing is negligible in the affected ear, as the function of the entire inner ear is destroyed.

Acroparaesthesia

Q.—*Is there any treatment for acroparaesthesia involving both fingers and toes in a woman of 65 who has to do all her own housework?*

A.—It is, of course, necessary first to exclude an organic neurological cause for acroparaesthesia—e.g., subacute combined degeneration. Assuming such causes to be excluded, acroparaesthesia as seen in middle-aged and elderly women is probably circulatory in origin and usually responds quite well to the following mixture:

℞	Liq. trinitrini	♏ 1
	Sod. brom.	gr. 5
	Acid. hydrobrom. dil.	♏ 10
	Aq.	ad ℥ss

Sig.: ℥ss t.d.s.

together with a small dose of thyroid extract, such as 1/2 grain a day. This treatment needs to be continued for several months.

Chemical Contraceptives and Endocrine Activity

Q.—*What is the method of choice of contraception in the case of a healthy woman of 27 who has had 2 children within 15 months? To what extent do chemical contraceptives inhibit vaginal absorption of the endocrine constituents of semen, and are these "endocrines" of real benefit to the woman?*

A.—Previous replies to the first part of this question appeared n the *Journal* of Aug. 5, 1944 (p. 198), Nov. 4, 1944 (p. 615), and Feb. 24, 1945 (p. 282), and should be consulted. In general it can be stated that the most suitable contraceptive in a case of this kind would be a Dutch vaginal pessary or a cervical cap, correctly fitted according to size, and combined with a chemical contraceptive such as phenyl mercuric acetate incorporated in a jelly or soluble pessary.

The second part of the question is more difficult. It was at one ime believed that the spermatozoa themselves can be absorbed by he epithelial cells lining the genital tract, and that the products of heir destruction have some form of beneficial effect on the female organism (Kohlbrügge's theory). This is no longer believed, and according to the evidence available there is no reason to think that he absorption of spermatozoa has any endocrine influence. The view current in some circles is that the fluid part of human semen contains some principle which, when absorbed by the vaginal (or uterine) epithelium, is of importance to the woman. Its reputed effects are mainly of a vague character, such as a sensation of well-being; but apart from any other function it may have it is claimed hat human seminal fluid promotes development or maturation of he female genitalia, especially the uterus, and thereby improves reproductive function. It is therefore argued that continued contraception leads to sterility, particularly if the method used is the condom or coitus interruptus. This view is based on scanty evidence, largely unconfirmed, and has only a few, but nevertheless ardent, advocates. While it is true that the vaginal epithelium can absorb hormones—e.g., oestrogens—and other substances, the majority believe that it has still to be proved that seminal fluid contains any special substance, hormonic or otherwise, whose absorption by the genital tract is of any value to the woman. Even if it has, the nature of the substance remains in doubt, and it is therefore impossible to say how it will be affected by chemical contraceptives. However, it seems unlikely that such contraceptives would have any direct chemical destructive action, and they should not interfere with the absorption of this hypothetical hormone unless they are of such a nature that they damage the vaginal epithelium, and are therefore to be avoided in any case.

Student House Officers

Q.—*What is the legal position of the student house officer as regards the ordering of dangerous drugs, and general "answerability" in law—e.g., actions at law?*

A.—The legal position of a student in hospital is very debatable, and has never been clarified by decision or statute. He must himself exercise a "reasonable" degree of skill and care, and may have damages awarded against him if his professional conduct in these respects falls below the standard to be "reasonably" expected, in the opinion of the court, of a student in his particular circumstances. How far the hospital governors, or his medical instructors or supervisors, can be held liable for his lack of skill or care probably depends on whether, in the particular case under review, the student at fault was allotted a duty which could "reasonably" be considered within his capacity. Perhaps hospital governors are not liable in any event, but instructors and supervisors almost certainly bear such a responsibility. As the circumstances of the particular case are all-important, the court would probably consider it reasonable to give students, in the difficult circumstances of wartime when qualified men are scarce, more responsible work than they would be given in time of peace.

In the particular matter of prescribing and supplying dangerous drugs, the law is that only "authorized persons"—for present purposes registered medical practitioners—may do so. Once the drug has been lawfully prescribed or supplied, it seems that anyone may lawfully administer it. In spite of the alteration in the conditions of hospital work, the Home Office has never extended the statutory authorization to students, and therefore a student may not lawfully prescribe or supply a dangerous drug except under the direct supervision of a qualified man. On the other hand, the authorities have not shown any disposition to inquire into the present practice in hospitals. Their attitude is doubtless the admirable one of letting a hard-pressed and necessary body of persons do their work as best they can without interference. Unless public anxiety is aroused by some mishap, the present position will probably be allowed to continue unquestioned.

Cold Pressor Tests

Q.—*What are cold pressor tests? Are they of any clinical value?*

A.—If one hand is immersed in ice water (4° to 5° C.) a rise of blood pressure averaging 9 mm. systolic and 7 mm. diastolic is normally observed. In certain people the rises may be of the order of 40 mm. and 30 mm. respectively. It has been claimed that such high figures are characteristic of hypertension or potential hypertension, but this view is not generally accepted. The response is not peculiar to cold, as similar pressor responses are obtained with other stimuli which produce discomfort or pain. There is no conclusive evidence that a hyper-reactive vasomotor system is correlated with a tendency to high blood pressure or arteriosclerosis, and cold pressor tests are therefore not of value in routine clinical work.

Anxiety and Obsessional Neuroses

Q.—*How does one distinguish an "anxiety neurosis" from an "obsessional neurosis"? What is the modern treatment for the latter?*

A.—The term "anxiety neurosis" is used in the Services to cover both what Freud calls "anxiety neurosis," when there is an excess of production of libido as against discharge, as in coitus interruptus, and anxiety hysteria (phobias, etc.), which are psychogenic. The term "anxiety states" may conveniently be used of all exaggerated anxiety, whether neurotic or otherwise (as in the "conditioned anxiety" from bombardments). Such terms may be most simply understood when viewed biologically. When an organism is faced with danger it reacts (*a*) by preparatory changes in the autonomic nervous system, and with a release of energy; (*b*) by a state of mental apprehension; and (*c*) by discharge of energy in voluntary motility through the central nervous system, whereupon the organism achieves its end and is restored to a state of equilibrium. Disorders of the first type are the psychosomatic disorders, such as nervous indigestion, palpitation, sweating, some headaches, etc. Disorders of the second type are the anxiety neuroses—generalized fear, the phobias, apprehension. Disorders of the third type are the conversion hysterias, which affect the functions of the central nervous system—such as hysterical blindness, deafness, anaesthesia on the sensory side, and paralysis on the motor side. Which of these is the symptom "chosen" depends on many factors, partly accidental, partly tending physically to the weak spot, but mostly influenced by childhood reactions and personality types. There may be, of course, and often are, mixed conditions. In addition to these there are the sexual aberrations and perversions, which are the emergence into activity of infantile modes of sensuous pleasure.

In our illustration we have taken the biological responses to fear, but the same physiological and psychological effects may result from other emotions like rage, which often produces headaches; but the mental part consists of hate or anger, not apprehension. Further, these same results may occur when the danger is subjective, from within, from fear of an impulse or from a memory, in which case the body suffers all the same changes and produces the same physiological results to prepare to meet objective changes which are not there.

The term "obsessional neurosis" is usually taken to refer to compulsive acts; but these may be of two types. In the first category come those impulses which are the emergence of some repressed aggression—e.g., the compulsion to strike or poison others, or the fear of doing so. Many tics are of this kind, for tics are aborted acts—e.g., the compulsion to strike may take the form of a tic of the arm. Obsessional neuroses of the second category are acts of a propitiatory kind—e.g., counting ten before speaking, walking on or over the cracks in the pavement, getting things exactly into line with the eyes. Over-conscientiousness and punctiliousness are obsessional character traits of the same order, being in essence propitiatory, and unconsciously designed to avert the dreaded consequences of forbidden desires. We may not know what these desires are, or that we are repressing them. But the necessity to keep them down means that we go to the opposite extreme—it may be, of over-punctiliousness, over-goodness, over-cleanliness—or that we resort to the performance of ritual acts. A mother, for instance, who for any reason does not want her child may feel guilty of this wish, and so become over-anxious about the child's health; or she may develop a phobia that she will poison the child; or she may start to sterilize unnecessarily everything the child uses, not in the least knowing why. Obsessions are therefore morbid mental compulsions due to a basic moral conflict.

The outward feature which distinguishes the obsessions from the other neuroses—e.g., hysteria and sex-perversions—is their compulsive nature; and, whereas the others are symptoms of some repressed tendency, the obsessional neurosis proper is primarily an act of the moral sense (or super-ego) *against* the repressed tendency. Reference should be made to the works of Freud, especially his *Introductory Lectures*. The modern treatment is obviously to discover the underlying guilt, which probably goes far back into childhood but which also persists at the present day, and to release the repressed emotion so that it might be used normally. But these are among the most difficult psychoneuroses to cure.

INCOME TAX

Payment for Services of Wife

E. S.'s wife has an income of £25 in the form of interest. How much can he pay her for professional services without her having to pay income tax?

*** The question is not affected by the amount of any "investment income" of the wife; that is deemed to be the husband's income for income-tax purposes. If E. S. pays his wife £89 for a particular year, the result will be that she has an "earned income" of £89 against which can be set the earned income relief (1/10th of £89) = £9 and the £80 special relief to married women's earnings, leaving nothing on which tax is due. If more than £89 is paid then tax begins to be payable.

Sickness Benefits

"OPTIMIST" refers to a previous reply on this subject to the effect that sickness benefits are not taxable, and points out that in the case of Forsyth *v.* Thompson (heard in 1940) the benefits were held by the court to be assessable.

*** The benefits referred to in the previous reply were those which are received for irregular and comparatively short periods. In Mr. Forsyth's case the benefits were permanent—as he had been permanently disabled from carrying on his profession. The legal distinction is that the former payments are not "annual payments," but the latter were so regarded and held to be liable as such to income tax. How long a non-permanent benefit would have to run to qualify as an "annual payment" is not known. It would, on the basis of the Forsyth judgment, depend to a large extent on the likelihood of its indefinite continuance.

LETTERS, NOTES, ETC.

Epileptic Fits in the Theatre

Dr. ROBERT CAIRNS (Barking) writes: Regarding the question of epileptic fits in the theatre (Jan. 27, p. 138) the possibility of endogenous hypoglycaemia should be considered. A detailed history may reveal that the patient frequently misses a meal when he visits the theatre or cinema, and his blood sugar is likely to be low. It would be interesting to inquire whether he eats sweets or drinks sweetened tea on such occasions, and if his attacks are prevented in this way. A low blood sugar during the night would account for his nocturnal attacks, and the nature and time of the last meal before retiring should be determined. Special investigations would include pre-breakfast blood sugar, glucose tolerance (6-hour curve), and be directed towards detecting any abnormality of pituitary, thyroid, adrenal, or liver function. An abnormal tolerance curve with the absence of any abnormality of these organs is suggestive of pancreatic hyperplasia or adenoma.

Rhubarb Leaves

Dr. S. CONCHUBHAIR (Dublin) writes: Dr. G. V. Ryan of Dublin states (Dec. 30, p. 876): "The leaves of rhubarb as a salad would probably be safe enough. Cooking them breaks down the fibres and releases the poison (oxalic acid) into the intestine. . . ." One might think from reading this that to eat raw leaves of rhubarb would be safe since oxalic acid would be released from them on cooking, but not otherwise, but this would be erroneous, as the raw leaves are poisonous; it is possible that one would not be likely to eat sufficient to be poisoned.

Translation, Please

Capt. S. S. B. GILDER writes: I find Dr. Burnet's notes under this head (Feb. 3, p. 174) rather confusing. During a recent enforced sojourn in the Reich I had many contacts with both French and German doctors, and I found that my French colleagues almost invariably used the word *charbon* for anthrax, and *anthrax* for carbuncle. The Germans use *Milzbrand* as a generic term for all types of anthrax and occasionally *Milzbrandkarbunkel* for the malignant pustule. Although their word for carbuncle is *Karbunkel*, they frequently loosely use the term *Furunkel* for lesions which, to British eyes, had long passed the stage of a folliculitis. I see that my *Lehrbuch der inneren medizin*, which gives English and French synomyms for many diseases, agrees with the above. It seems clear, however, that in earlier days failure to recognize the difference between a malignant pustule and a carbuncle led, as Dr. Burnet says, to an indifferent use of the same word for both conditions.

Mr. GEO. H. BELL (London, S.E.4) writes: The following extracts may help Dr. Maurice McElligott (Jan. 13, p. 70). I give only those phrases which define the words.

French:

Larousse XX^e^ Siècle, vol. II, p. 141: Charbon, maladie infectieuse causée par l'inoculation de la bactérie charbonneuse . . . pustule maligne. . . .

Garnier et Delamare, *Dict. de Termes Techniques de Médecine*, p. 107: Charbon, fièvre charbonneuse . . . bactéridie charbonneuse.

German:

Der Kleine Brockhaus, p. 464: Milzbrand (Anthrax), akute, durch den Milzbrandbazillus verursachte Infektionskrankheit. . . .

Dornblüth, *Klinisches Wörterbuch*, p. 35: Anthrax, Milzbrand . . . mit Bildung einer Pustel, *Pustula maligna*, Milzbrandkarbunkel . . . Erreger, Milzbrandbazillus = *Bacillus anthracis*.

Spanish:

Espasa-Calpe, *Diccionario Enciclopedico*, vol. I, p. 790: Carbunco, . . . el carbunco o pústula maligna es una enfermedad originaria por el *Bacillus anthracis*.

Larousse, *Diccionario de Medicina usual*, p. 413: Pústula maligna o carbunco (Bacteridia carbuncosa).

Neither of the last two works mentions the word "carbón" with the meaning of anthrax, although the latter is translated from French and the obvious rendering of "charbon" would be "carbón," if such a term were really Spanish. But Spanish has suffered, perhaps more than any other language, by being flooded with the barbarisms of careless translators; "carbón" may be among them.

Dr. James Burnet (Feb. 3, p. 174) introduces another language and another subject. It may be helpful, therefore, if I give the most usual terms for (*a*) the disease caused by *Bacillus anthracis* and (*b*) the ordinary carbuncle:

(*a*) Anthrax.—French: *Charbon* (pustule maligne). German: *Milzbrand* (pustula maligna). Italian: *Carbonchio* (pustula carbonchiosa). Spanish: *Carbunc(l)o* (pústula maligna).

(*b*) Carbuncle.—French: *Anthrax*. German: *Karbunkel*. Italian: *Antrace*. Spanish: *Antrax*.

THERAPEUTIC TRIAL OF METHIONINE IN INFECTIVE HEPATITIS*

BY

CLIFFORD WILSON, D.M.

Major, R.A.M.C.

M. R. POLLOCK, M.B., B.Chir. AND **A. D. HARRIS, M.R.C.S., L.R.C.P.**

During the present war there has been a greatly increased incidence of liver disease due to infective hepatitis, arsenotherapy jaundice, and homologous-serum jaundice following inoculation with yellow-fever vaccine. The problem of treatment has produced a renewed interest in the relation of dietary factors to liver disease. Most animal experiments recorded in the literature have been concerned with the production of cirrhosis of the liver and its relation to the fat content of the diet or to liver metabolism of fat. More recently, however, certain protein constituents have been shown to have an important bearing on the production of acute liver damage. Davis and Whipple (1919) found that skimmed milk or casein protected the liver against the toxic action of chloroform. Subsequent work (Miller, Ross, and Whipple, 1940; Miller and Whipple, 1942) revealed that the sulphur-containing amino-acids, particularly methionine, were the specific protective factors. These experiments were performed in dogs fed on a very low protein diet. Messinger and Hawkins (1940) found that in dogs a high protein diet protected the liver against the toxic action of arsphenamine; and Goodell, Hanson, and Hawkins (1944), using a similar technique to that of Miller and his colleagues, showed that methionine exerted a specific protective action against mapharside. More recently it has been discovered that protein deprivation alone gives rise to acute liver damage, which can be prevented by the addition of sulphur-containing amino-acids to the diet. Daft, Sebrell, and Lillie (1942) reported that cystine and methionine prevented the hepatic haemorrhages and necrosis which occur in rats on a low-protein high-carbohydrate diet. Himsworth and Glynn (1944) demonstrated that this protective action was independent of other dietary factors.

From these experiments it is apparent that protein deprivation in animals produces or predisposes to acute hepatic necrosis and that the sulphur-containing amino-acids, particularly methionine, protect the liver from the effects of protein deficiency. It was on the basis of these experiments that the present therapeutic trial of methionine was undertaken. The object of the trial was to discover whether oral administration of the amino-acid had a beneficial effect on the course of the disease and, in particular, whether the period of incapacity could be shortened.

Material

The trial was carried out on 100 Service patients with infective hepatitis, admitted to hospital under the M.R.C. Jaundice Unit. Methionine was administered to alternate cases. All were males, except three in the treated group and two in the control group. The average duration of symptoms of all cases on admission was 8.3 days, the average interval between the appearance of dark urine and admission was 3.9 days, and the majority of the patients had been jaundiced one to two days.

Methods

dl-methionine was given in daily doses of 5 g. from the time of admission until the urine had been bile-free (using the foam test) for five days. This quantity of methionine is probably roughly equal to the average content of the normal diet. The amino-acid was administered in morning and evening doses of 2.5 g. each. A fresh solution was made daily, kept in the refrigerator, and given ice-cold, flavoured with orangeade. Control subjects received orangeade alone. There was no restriction of diet except that greasy foods were omitted, and all patients received a supplementary pint of milk and one egg daily. It was impossible to give a fixed diet owing to variation in the appetite at different stages of the disease. Sample analyses showed that during the period of diminished appetite (i.e., during the first few days after admission) the amount of food actually consumed contained approximately 60 g. protein, 70 g. fat, and 240 g. carbohydrate, with a total calorie value of 1,900. During the later stages, after the appetite had returned to normal, the values were 120 g. protein, 130 g. fat, 450 g. carbohydrate; calorie value 3,500. The majority of patients were kept in hospital until they were fit to resume training at a convalescent depot, from which they returned for examination one month after discharge from hospital.

Comparison of the treated and control groups was based on clinical and biochemical criteria. The clinical criteria were: (1) duration of anorexia after admission; (2) duration of jaundice after admission; (3) duration of liver enlargement after admission; (4) duration of liver tenderness after admission; (5) period in hospital; (6) frequency of relapses or recrudescences. The majority of relapses or recrudescences were observed before discharge from hospital; we have included any deterioration of the patient's condition during recovery which led to a return of symptoms with increase in biliuria and rise in the serum bilirubin.

The biochemical criteria employed were: (1) duration of biliuria; (2) interval between admission and return of serum bilirubin to 2 mg. per 100 c.cm.; (3) maximum serum bilirubin; (4) hippuric acid synthesis after the disappearance of bile from the urine, as a test for recovery of liver function. The foam test for bilirubinuria was used, and serum bilirubin was estimated by the method of Malloy and Evelyn (1937). The intravenous modification (Quick, 1939) of the hippuric acid synthesis test was employed.

Comparability of Control and Treated Cases

The following criteria were used to determine whether the control and treated cases were comparable: (1) age; (2) interval between first symptom and admission; (3) interval between appearance of dark urine and admission; (4) percentage of cases admitted with rising serum bilirubin.

TABLE I.—*Comparability of Treated and Control Groups*

	Treated	Controls	Difference	D./S.E.
Number of cases	50	50		
Age (mean in years)	26·7	27·2	0·5	0·42
Onset to admission (mean in days) ..	7·5	9·2	1·7	1·84
Dark urine to admission (mean in days)	4·4	5·7	1·3	2·14
Number of cases with rising serum bilirubin on admission	25	25		

The comparative figures for the two groups are given in Table I. The age distribution was very similar, with mean

---

* A report to the Medical Research Council.

4394

values of 27.2 (controls) and 26.7 years (treated cases). The mean duration of the disease before admission was a little shorter in the treated group (7.5 against 9.2 days), which might produce a slight bias in favour of the untreated cases in respect of criteria measured from the date of admission. There were 29 patients in the treated group with less than seven days' history on admission, compared with 23 in the control group: as will be seen later, comparison of these early cases does not give significantly different results from those obtained by comparison of all cases. Thus the groups may be regarded as comparable in spite of the shorter mean duration before admission in the treated cases. Furthermore, the duration of the disease before admission is largely determined by the length of the pre-icteric stage; this we have found to bear no relation to the severity or duration of the icteric stage, on which our comparison is mainly based. In both groups exactly half the cases showed a rising serum bilirubin after admission. This is not an entirely satisfactory criterion, since estimations were made on admission and every third day subsequently, so that if methionine had an immediate beneficial effect a rising serum bilirubin on admission might have been checked in some cases. The general results of the investigation indicate that such an occurrence is unlikely. On the several criteria employed, it may therefore be assumed that the control and treated groups are comparable.

Results

A comparison of the clinical and biochemical criteria in treated and untreated patients is made in Table II. Figures are given for all cases, and for early cases admitted with less than seven days' history of symptoms. The majority of criteria show a slight bias in favour of the methionine-treated group, but the differences are not statistically significant.

TABLE II.—*Comparison of Clinical and Biochemical Criteria of Severity and Duration in Treated and Control Groups*

	All Cases				Early Cases			
	Treated	Controls	Difference	D./S.E.	Treated	Controls	Difference	D./S.E.
Number of cases ..	50	50			29	23		
Duration of anorexia (days)	8·3	8·7	+0·4	0·17	7·7	10·7	+3·0	0·79
Duration of jaundice (days)	16·0	18·6	+2·6	0·96	17·9	17·8	−0·1	0·02
Duration of liver enlargement (days)	20·8	23·9	+3·1	0·67	21·6	24·2	+2·6	0·40
Duration of liver tenderness (days)	21·5	22·8	+1·3	0·47	20·5	24·8	+4·3	0·67
Period in hospital (days)	32·0	36·4	+4·4	1·33	33·9	32·1	−1·8	0·35
Number of relapses	5	9	+4	1·14				
Duration of bilirubinuria (days)	13·2	16·7	+3·5	1·59	14·8	17·0	+2·2	0·55
Duration of hyperbilirubinaemia (days)	18·1	21·9	+3·8	1·20	21·1	20·2	−0·9	0·19
Maximum serum bilirubin (mg./100 c.cm.)	12·0	12·3	+0·3	0·20	12·0	12·2	+0·2	0·11
Final hippuric acid test	1·039	1·058	−0·019	0·36	1·007	1·125	−0·118	1·49

+ = Difference in favour of treated cases. − = Difference in favour of controls. Early cases were admitted within 7 days of onset. All figures except number of relapses are mean values. Time intervals are measured from admission —i.e., from the beginning of treatment. Duration of hyperbilirubinaemia is the interval between admission and return of serum bilirubin to 2 mg./100 c.cm. Hippuric acid test is expressed as grammes of sodium benzoate excreted in 1 hour.

The mean duration of jaundice after admission was 16.0 days in treated patients and 18.6 days in controls. This is not a significant difference (D./S.E.=0.96). In early cases the difference was negligible (17.9 against 17.8 days). Duration both of liver enlargement and of liver tenderness was again slightly longer in the control than in the treated series, and the early cases showed a similar but not significant difference. Duration of stay in hospital was 4.4 days shorter in the treated group (32.0 days) compared with the controls (36.4 days); in early cases the difference was reversed (33.9 days, treated; 32.1 days, controls). There were five relapses in the treated group, compared with nine in the control group, but this difference is less than twice the standard error (D./S.E.=1.14). Duration of anorexia was almost the same in the two groups (8.3 days, treated; 8.7 days, controls), although in early cases anorexia lasted 3 days longer in controls.

Comparison of the biochemical criteria showed similar small differences in favour of the treated group. The duration of bilirubinuria after admission was 13.2 days, treated, against 16.7 days, controls (D./S.E.=1.59); in the early cases the difference was somewhat smaller (14.8 against 17.0 days). The duration of hyperbilirubinaemia after admission showed a similar but not significant difference (18.1 days, treated; 21.9 days, controls; D./S.E.=1.2); this difference was reversed when early cases were compared (21.1, treated; 20.2 days, controls). The difference in duration of hyperbilirubinaemia was more pronounced in cases admitted with a falling serum bilirubin, which is partly explained by the fact that in these the mean admission serum bilirubin was higher in the control (7.65 mg. per 100 c.cm.) than in the treated group (5.9 mg. per 100 c.cm.), so that half the control cases started with a disadvantage, estimated at 2½ to 3 days, compared with the treated cases.

The mean maximum recorded serum bilirubin was almost identical in the two groups. The comparison of maximum serum bilirubin was confined to the 25 cases in each group admitted with rising serum bilirubin. If, instead of comparing the mean values, the cases with rising serum bilirubin on admission are subdivided into groups with maximum serum bilirubin of 0 to 5, 5 to 10, and over 10 mg. per 100 c.cm., the distribution of cases in these groups of differing severity is very similar in the treated and untreated series (Table III).

TABLE III.—*Distribution of Cases admitted with Rising Serum Bilirubin, according to Maximum Observed Serum Bilirubin*

Maximum Serum Bilirubin	Treated	Controls
0–5 mg./100 c.cm.	1	1
5–10 mg./100 c.cm.	10	7
Over 10 mg./100 c.cm.	14	17
Total	25	25

The hippuric acid test, performed at the end of treatment, showed no significantly different mean value in treated and control cases; in fact, the result was slightly favourable to the controls.

Discussion

One of the difficulties in interpreting the results of therapeutic trials in infective hepatitis is the choice of suitable criteria for comparison. In individual cases of the disease there often appears to be a very variable relationship between the clinical and biochemical findings. We have attempted to overcome this difficulty by comparing as many criteria as possible, so as to obtain a comprehensive picture of the severity and duration of the disease. In a study of over 200 cases we have found that in a large series there is in fact a fair correlation between the clinical and the biochemical criteria of severity used in this comparison.

Although the differences between treated and untreated cases do not appear to be statistically significant, the fact that all the criteria except hippuric acid synthesis show some bias in favour of the treated group suggests that possibly the methionine may not have been without benefit. Since, however, many of the criteria are interdependent their values should not be summated in assessing the effect of methionine treatment. Thus duration of jaundice and duration of biliuria are dependent on duration of hyperbilirubinaemia; and length of stay in hospital, except in a few cases, was decided by the time taken for the serum bilirubin to reach the 2-mg. level.

We conclude, therefore, that oral administration of methionine under the conditions of this trial had no significant effect on the severity or duration of the disease. It must be pointed out that infective hepatitis is rarely diagnosed until jaundice becomes manifest. Even if treatment is started on the first day of jaundice, symptoms may have been present for a week or more, and both symptoms and liver function tests are rapidly improving in the majority of cases. It is apparent that methionine administration does not prevent relapses. We observed five relapses during the course of methionine therapy, and there was no evidence that the degree of liver involvement during these relapses was less than in untreated subjects. Himsworth and Glynn (1944) have suggested that massive hepatic necrosis occurring in the course of infective hepatitis may be due to nutritional factors. The rarity of this complication would make it extremely difficult to decide this point. It has been stated (Cohen, 1944) that methionine undoubtedly has beneficial effects in "subacute necrosis" of the liver. The proof of this would again demand a large and well-controlled series of cases. In our limited experience methionine has been ineffective in patients who had already developed symptoms of hepatic failure.

Summary

Five grammes of methionine has been administered daily by mouth to alternate cases in a series of 100 Service patients with infective hepatitis. A comparison of clinical and biochemical criteria has shown no significant effect on the severity or duration of the disease or on the incidence of relapses.

TREATMENT OF INFECTIVE HEPATITIS WITH METHIONINE

BY

G. HIGGINS, J. R. P. O'BRIEN, R. A. PETERS, ALICE STEWART, AND L. J. WITTS

(From the Department of Biochemistry, and the Nuffield Department of Clinical Medicine, Oxford)

No therapeutic means have yet been found capable of producing a rapid alleviation of infective hepatitis. There would seem to be justification for seeking such a means among the constituents of proteins. Favourable effects of a diet of high protein and vitamin content have been claimed by some investigators in cases of liver disease (Patek and Post, 1941). In animals it has been shown experimentally that the health of the liver and its capacity to resist the action of toxic agents are influenced by the protein content of the diet (Himsworth and Glynn, 1942). Diets low in protein may produce in animals a cirrhosis of the liver which in many features resembles that seen in man (György and Goldblatt, 1939; György, 1944; Lillie, Daft, and Sebrell, 1941). Of the amino-acids, methionine has proved most effective in preventing the experimentally induced deposition of fat in the livers of animals (for references, see McHenry and Patterson, 1944) and the cirrhosis associated with a low protein intake (György, 1944). From the work of Miller and Whipple (1942), who described its value in preventing necrosis of the liver following chloroform anaesthesia, methionine may have some value in protecting the liver against other toxic substances. In what way methionine acts in these conditions, whether by processes of transmethylation or by a role in sulphur metabolism, is uncertain. Nevertheless, of all the amino-acids, methionine most justifies a trial of its effect upon liver disease in man. Peters *et al.* (1945) have given evidence of a slight beneficial effect of methionine and cysteine upon so-called post-arsphenamine jaundice. While that trial was in progress it seemed worth while to ascertain its usefulness in infective hepatitis.

Details of Trial

All patients suffering from infective hepatitis referred to the hospital between Oct., 1943, and March, 1944, were admitted to the same ward. The total number was 37, and their ages were between 17 and 45 years. Care was taken to exclude patients with liver disease from other causes; no patient who had received neoarsphenamine or who had been exposed to any toxic substance was included in the experimental group. All the patients were kept in bed. Every alternate patient was given methionine. They were not discharged until clinically well and their plasma bilirubin had fallen below 2 mg. per 100 c.cm.[*] One month after discharge they were seen again and their blood and urine examinations were repeated.

To minimize the chance variation of the methionine content of the meals, all patients, treated and untreated, were put on a diet of low-fat, high-protein content, supplemented with extra vitamins. A record was kept of the amount eaten by every patient at each meal. It was estimated that the methionine content of the diet consumed daily was of the order of 2.5 g. To ensure an adequate supply of methionine twice this amount was given to the treated patients. Synthetic *dl*-methionine is not easily taken in solid form. It was therefore made up in the proportions of 10 g. to 283 ml. of water containing 2.8 ml. of concentrated hydrochloric acid; this solution contained 1 g. of methionine in 1 fl. oz. Throughout the day five 1-g. doses were given either in milk or after flavouring with fruit juice. Including that in the diet, the treated patients received daily nearly 7.5 g. of methionine. Some found the amino-acid nauseating, and in others it caused vomiting in the early days of the disease. There was only one instance of a patient's intolerance to the amino-acid. During the experiment one of us (G. H.) developed infective hepatitis. He was admitted to the ward and was given methionine. This induced persistent nausea. He became so intensely jaundiced and ill that the drug was stopped after 7 days. For this reason his case is not included in the series, but is described separately.

A detailed biochemical study was made on all patients. It included blood urea, plasma bilirubin, proteins, phosphatase determinations at 2–3-day intervals, daily urinary excretion of nitrogen, urea, creatinine, creatine, porphyrin, bilirubin, and urobilin, and faecal porphyrin and stercobilinogen studies. A detailed description of these findings will be published later. Only the more simple biochemical investigations, which were thought to reflect adequately the clinical course of the disease and provide criteria for comparing the treated and untreated groups, are being reported here.

Results

In a small series it might happen that all the treated cases were much milder or much more severe than the controls, or that the former were all admitted much earlier or later in the course of the disease than the others. Table I has been compiled to show that in the present series there was no great bias in either group. The treated cases, omitting G. H., included 8 males and 10 females, and the controls 11 males and 7 females. If the severity of the disease be judged by the degree of bilirubinaemia it will be seen that there were 6 severe, 8 moderate, and 4 mild cases in the treated group, and 8 severe, 5 moderate, and 5 mild cases in the control group. This table also shows that in 9 of the treated cases and 10 of the controls the jaundice increased after admission, which suggests that the illness was at about the same stage in both groups when treatment was started. In further support of this is the fact that the length of time from the onset of the illness to the day of admission, which is given in Table II, is not significantly different in the two groups.

Table I.—*The Severity of the Bilirubinaemia in 18 Controls and 18 Treated Subjects, and the Number of Subjects in which the Bilirubinaemia Increased after Admission*

	Number of Subjects	
	Treated	Controls
Males	8	11
Females	10	7
Highest level of plasma bilirubin:		
1. Over 10 mg./100 c.cm.	6	8
2. 10 to 6 mg./100 c.cm.	8	5
3. Under 6 mg./100 c.cm.	4	5
Rising plasma bilirubin	9	10

From a consideration of the detailed clinical, biochemical, and haematological studies made during the course of the illness and at the follow-up, it was decided that the duration of anorexia, raised plasma bilirubin, and biliuria provided adequate information for the assessment of the therapeutic value of methionine in infective hepatitis. All the patients were afebrile either before or immediately after admission, and there was no consistent change in the pulse rate, white cell count, or sedimentation rate that might have provided alternative criteria of ill-health. The results from all the cases, except G. H., are summarized in Table II, which gives the length of time after the cases came under observation until: (1) the patient ate at least 2,000 calories a day; (2) the plasma bilirubin fell below 2 mg. per 100 c.cm.; (3) the bile disappeared from the urine. It will be observed that there was no difference in the two groups in respect of these three criteria.

---

[*] Plasma bilirubin was estimated by the method of Thannhauser and Andersen (1921).

TABLE II.—*Duration (in Days) of Anorexia, Bilirubinaemia, and Biliuria*

	Subjects	
	Treated	Controls
Duration of illness before admission ..	8·4 ± 0·61	8·6 ± 0·29
After admission:		
1. Food intake less than 2,000 calories	8·3 ± 0·79	8·06 ± 1·15
2. Plasma bilirubin over 2 mg./100 c.cm.	9·8 ± 0·97	9·9 ± 1·36
3. Biliuria	8·6 ± 0·55	7·2 ± 0·96

In each instance the average number of days, with the standard error, is given or the treated and untreated cases.

It might be argued that in the mild cases the slightness of the illness would make difficult a demonstration of the therapeutic effect of methionine. Consequently the results of the investigations upon the 10 most severely jaundiced patients from each group were considered. They are given in Table III.

TABLE III.—*Analysis of the Results Obtained on the 10 Most Severely Jaundiced Cases in Each Group. (Average Values, with the Standard Error)*

	Subjects	
	10 Treated	10 Untreated
Maximum plasma bilirubin (in mg./100 c.cm.)	14·5 ± 1·42	14·5 ± 1·36
Plasma bilirubin over 2 mg. (in days) ..	12·8 ± 0·88	14·1 ± 1·27
Bile in urine (in days)	8·8 ± 0·56	8·9 ± 1·77
Anorexia (in days)	8·7 ± 0·7	8·1 ± 1·67
Number of cases of rising bilirubin	5	8
Time from maximum bilirubin to bilirubin below 2 mg./100 c.cm.	9·6 ± 1·2	11·6 ± 1·42

The average duration of the raised bilirubin in the plasma was 14.1 days in the controls and 12.8 in the treated cases, but the individual variation was so great that the difference was less than the standard deviation. The average duration of the anorexia in the treated cases was 8.7 days, compared with 8.1 in the untreated cases; clearly the difference is negligible. Five of the treated cases continued to have a rising bilirubinaemia after admission, compared with 8 of the controls; and there was no difference in the number of days that the bile was present in the urine in the two groups. The average time taken for the plasma bilirubin to fall from its maximum height to below 2 mg./100 c.cm. was 9.6 days in the treated and 11.6 days in the control cases.

Case G. H. differed from the others in the severity and duration of the jaundice. The highest plasma bilirubin concentration determined in the other 36 cases was 24 mg./100 c.cm., and no one remained jaundiced for more than 22 days after admission. In G. H. the plasma bilirubin rose to 32 mg. and remained high for 45 days. Throughout the week that the methionine was given, the jaundice steadily increased and the nausea induced by the amino-acid appeared to have such an unfavourable effect that it was stopped. The peak of the jaundice was reached on the 12th day after admission and the plasma bilirubin remained about 30 mg./100 c.cm. for another 10 days. The patient eventually made an uninterrupted recovery.

Discussion

In a disease in which the mortality rate is low the length and severity of the illness should be appreciably less in treated cases than in untreated ones if the specific remedy produces an effect. The natural course of the disease in infective hepatitis is so variable and the tendency to spontaneous cure so universal that it is almost impossible to decide in any individual case whether the illness has been affected by the treatment. But a comparison of two groups of cases of about equal severity should reveal the presence or absence of a therapeutic effect if one group is treated and the other not, even though it might require a much larger number of cases to show that an apparent effect was statistically significant.

In this trial only slight differences were seen between the patients treated with methionine and those who received none, and, therefore, though the cases were few the amino-acid produced less effect than in the trial reported by Peters *et al.* (1945). This suggests that methionine is clinically of little practical importance in infective hepatitis. In this respect our experience appears to differ from that of Beattie and Marshall (1944a, 1944b) in the treatment of post-arsphenamine jaundice with sulphur-containing amino-acids.

The prophylactic value of methionine has been well established in animals in which liver damage has been produced by the use of diets rich in fat, by reduction of protein intake, or by exposure to noxious substances. These conditions would not seem to apply to the majority of patients suffering from infective hepatitis. Biochemical studies of the plasma protein indicate that reduction in protein intake is not an aetiological factor in the disease, and wartime feeding restricts a high fat intake. Considered from this point of view, the treatment of infective hepatitis with methionine might not be expected to be very efficacious. But there is another possibility. The liver damage had occurred before the patients, already jaundiced, were admitted to hospital for treatment. Methionine might hasten the repair of the damaged cells. This effect, if any, would appear to be too slight to be of clinical significance, for no statistical difference in the time taken to pass from the stage of maximum jaundice was observed between the treated and untreated groups. Although the results of our trial do not suggest that methionine in quantities of 7½ g. daily produces any demonstrable benefit, it is possible that our experimental conditions were not suitably designed for its manifestation. Nevertheless, it will rarely be practicable to treat a high proportion of cases of infective hepatitis at an earlier stage in the disease than was studied in the present experiment.

Summary

Eighteen patients suffering from infective hepatitis were treated with a low-fat high-protein diet with extra vitamins, and another 18 with the same diet supplemented with 5 g. of pure methionine.

The two groups were comparable in respect of the duration of the illness before admission to hospital and of the number of mild and severe cases.

Treatment with methionine did not significantly affect the clinical course of the illness, the anorexia, or the average duration of biliuria or of bilirubinaemia.

We are indebted to M. W. Stanier, J. Badenoch, B. Glascock, W. Wakelin, L. A. Rawlings, and P. Quelch for practical assistance: we are also grateful to R. H. S. Thompson for advice. This trial was made possible by the generous supply of synthetic methionine by the Ministry of Supply.

The Ministry of Health has sent to all local authorities and port health authorities a folder giving details of new publicity material available for local use in support of the educational campaign on venereal diseases. The central publicity undertaken during the past two years by the Ministry, in conjunction with the Ministry of Information and the Central Council for Health Education, is being continued; and recently large posters have been displayed on hoardings throughout the country with the object of drawing public attention to the seriousness of the problem, and of increasing the effectiveness of the detailed education carried out through advertisements, films, lectures, leaflets, etc. The display of posters on the subject of venereal diseases, undertaken for the first time in this country, has aroused no criticism, and there is evidence that the campaign as a whole continues to have the approval of the vast majority of the public. The Minister considers it important to maintain this educational publicity during the next twelve months, and to intensify it.

THE ANTIDIURETIC ACTION OF NICOTINE AND OF SMOKING

BY

J. H. BURN, M.D., F.R.S.
Professor of Pharmacology

L. H. TRUELOVE, B.A.

AND

ISABEL BURN, B.A.

(From the Department of Pharmacology, Oxford)

Nicotine has been well known since the time of Langley as a substance which stimulates the ganglia of the sympathetic system. Langley painted a solution of nicotine on a ganglion to determine what effects followed the stimulation of the cells present in it. He was thus able to locate the synaptic connexions of the sympathetic system. When nicotine is injected intravenously the stimulation of the ganglia results in a rise of blood pressure and a raised pulse rate. Nicotine also stimulates the carotid body, and so increases respiration. Finally, nicotine in sufficient doses produces convulsions. The experiments to be described show that, in addition to these properties, nicotine has an antidiuretic action, probably due to stimulation of the hypothalamus, and that man is so sensitive that the action can readily be demonstrated in some subjects after one cigarette.

In 1939 Dr. Mary Pickford demonstrated that when a diuresis is produced in a dog by giving it water, the diuresis is promptly inhibited by the intravenous injection of acetylcholine. To observe the effect a large dose—1 mg.—was used, and to exclude the action on the heart, on the blood vessels, and on the intestines atropine was given to the dog beforehand. The antidiuretic effect was shown to be due to the liberation of the hormone of the posterior lobe of the pituitary gland, because when the posterior lobe was removed the injection of acetylcholine no longer inhibited a diuresis.

Since this effect of acetylcholine was exhibited in the presence of atropine, it seemed likely to belong to those effects of acetylcholine which Dale (1914) called nicotine-like. If so, it was to be expected that nicotine itself would exert a similar action.

Observations on Rats

Experiments were therefore performed with groups of 16 rats to which water was given by stomach-tube to produce a diuresis (Burn, 1931); the antidiuretic action of acetylcholine was confirmed, and it was then found that the intravenous injection of 0.1 mg. of nicotine acid tartrate, given 45 minutes after the water, inhibited the diuresis during 45 minutes. The least dose of nicotine which, given subcutaneously, would exert an antidiuretic action was next found. In Fig.[1] 1 is shown a composite record of two experiments on 16 rats. They were males, about 190 g. in weight; after being kept without food overnight they were each given warm water by stomach-tube (5 c.cm. per 100 g.) and put in four cages for urine collection. The urine was recorded every 15 minutes. After 30 minutes from giving the water, 8 of the rats were injected with nicotine acid tartrate, 0.5 mg. per 100 g. The other 8 were injected with saline. The experiment was repeated on another day, when the rats previously injected with nicotine were injected with saline, and vice versa. Fig. 1 shows that rats when injected with nicotine had a larger diuresis than the controls during the next 15 minutes, but the diuresis was then inhibited for about 45 minutes. Thus the curve showing the diuresis when the control injection of saline was given is a curve with a single peak 75 minutes after the water was given; the curve when nicotine was injected is a curve with two peaks, in between which is the inhibition due to the injection of nicotine. When the experiment was repeated with half the dose of nicotine, no inhibition was seen.

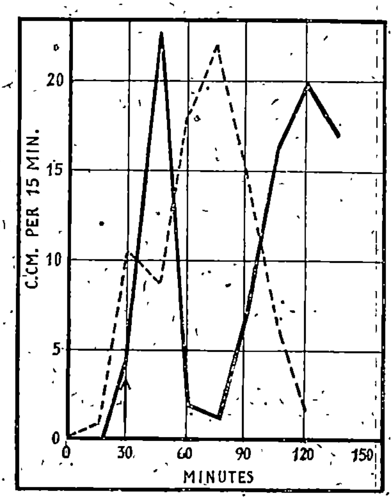

FIG. 1.—The broken line shows course of excretion of water given by stomach-tube to 16 rats at zero. The solid line shows course of excretion when each rat received 0.25 mg. nicotine (base) by subcutaneous injection 30 min. after it received water. Note period of inhibition between the two peaks of excretion.

It is very probable that the increased excretion seen as the first peak in Fig. 1 immediately after the nicotine is explained by a rise of blood pressure due to the nicotine. This rise would increase the rate of diuresis. In support of this explanation is the observation that when a similar experiment to that shown in Fig. 1 was performed using tyramine instead of nicotine, the peak of the diuresis occurred earlier than in the controls, though when tyramine was injected there was no period of inhibition and therefore no second peak. Tyramine causes a rise of blood pressure as does nicotine, but by a purely peripheral action on heart and vessels.

Effect of Pituitary Removal

The main point of interest, however, was the inhibition of diuresis between the two peaks in Fig. 1. It was next shown that no such inhibition occurred when rats from which the pituitary gland was removed were used instead of normal rats. We are indebted to Dr. Edith Bülbring for preparing hypophysectomized rats for this work. These rats were injected daily with anterior pituitary extract kindly sent to us by Dr. I. W. Rowlands of the National Institute for Medical Research. They were given water by mouth (6 c.cm. per rat) in the morning of each day, and observations on water diuresis were then made in the afternoon after giving more water (6 c.cm. per rat). The graph in Fig. 2 shows that the injection of nicotine in the same dose and at the same time as in Fig. 1 failed to produce any inhibition of diuresis. When the experiments were complete the rats were killed and the pituitary fossa of each was examined for remnants of gland. None were found. This result made it clear that the action of nicotine in exerting the antidiuretic effect depended on the presence of the pituitary gland, and probably on the posterior lobe.

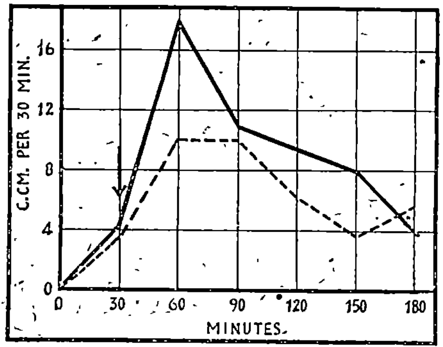

FIG. 2.—A similar experiment to that in Fig. 1, carried out on 10 rats from which the pituitary body had been removed. The broken line represents the control experiment, the solid line the experiment in which nicotine was injected. There is no phase of inhibition.

Nicotine is not the only alkaloid which exerts this antidiuretic action, for de Bodo (1944) has found that morphine has a similar action in the dog, exerted through the neurohypophysis.

Observations on Man

The least dose of nicotine which, given subcutaneously, produced an antidiuretic effect in rats was 0.5 mg. of the acid tartrate per 100 g.: this corresponds to 0.25 mg. of nicotine base per 100 g. If man were equally sensitive per unit of body weight, 150 mg. of nicotine base would be required to exert an effect on a man of 60 kg. Despite the unlikelihood of observing a positive result in man, it seemed worth while to determine whether the smoking of cigarettes had an antidiuretic effect. In performing the experiment the subject, when his stomach was empty, passed water every 15 minutes and recorded the volume. When this was reasonably uniform he drank one litre of warm water and continued to pass water every 15 minutes. The excretion rose to a peak usually about 75 or 90 minutes after drinking the water and then fell to the original rate of excretion in about 2½ hours from the time of drinking. In Fig. 3, curve A shows the normal diuresis thus obtained in E. M. V. W. Curve B shows the course of the diuresis in E. M. V. W. when he smoked three cigarettes in succession, beginning 45 minutes after drinking the water. The diuresis had already begun when smoking started, but inhibition occurred after 15 minutes, and the effect of the three cigarettes was to produce complete inhibition during 2.5 hours; after which the diuresis began again to reach a peak 4.5 hours after drinking the water. E. M. V. W. is a healthy male of 26 years. In smoking the three cigarettes, he did so as rapidly as possible and inhaled deeply. He smoked them in 20 minutes. He suffered from vertigo and felt very sick; 5 minutes after finishing smoking he vomited, and continued to feel sick for one hour. The inhibition of the diuresis outlasted these symptoms, and in several other observations an inhibition was observed without the production of any appreciable symptoms at all. Thus in Fig. 5 an observation on the same subject—E. M. V. W.—is recorded, in which inhibition was produced by one cigarette; he noted "slight dizziness" while he smoked, but nothing more.

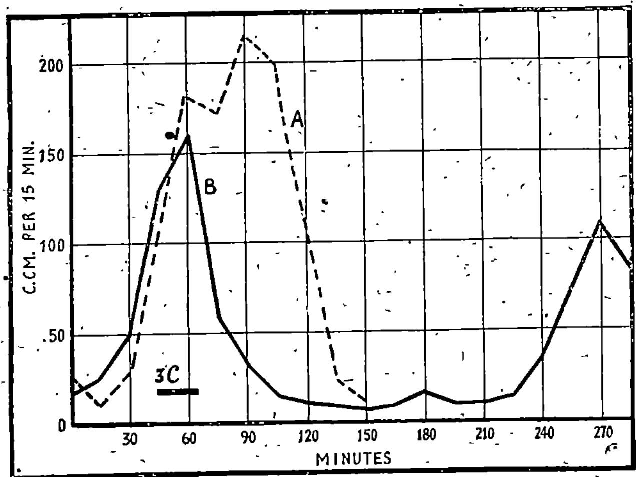

FIG. 3.—Subject E. M. V. W. drank 1 litre of water at zero. The broken line shows excretion of water in c.cm. per 15 min. The solid line shows excretion in a second experiment when he smoked 3 cigarettes, beginning 45 min. after drinking the water. Note the long period of inhibition.

Variation among Subjects

This antidiuretic effect of smoking varied a good deal in different subjects. Subject E. M. V. W. was unusually sensitive, for, as seen in Fig. 5, the smoking of one cigarette produced an effect on him. Subject L. H. T., observations on whom are shown in Fig. 4, was less sensitive than E. M. V. W., for the smoking of one cigarette had no effect. In another subject, G. B. P., who was a fairly heavy smoker, the smoking of three cigarettes had only a very slight effect. However, out of seven subjects, six of whom were males between 20 and 26, one cigarette had an inhibitory effect on diuresis in three, two cigarettes had an inhibitory effect in two others, and three cigarettes had an inhibitory effect in a sixth. Only G. B. P. can be considered as scarcely affected by three cigarettes. He smoked about 20 cigarettes a day in addition to two or three pipes. Another subject who was a regular pipe smoker observed no inhibitory effect from smoking a pipe; on the contrary, he observed an increased rate of excretion, probably due to the rise of blood pressure which the smoking caused. A positive effect was recorded only when as a result of smoking there were two peaks of diuresis as shown in Figs. 3, 4, and 5, and the time interval between these peaks is expressed as "delay" in the accompanying Table.

Table showing Experimental Results

Subject	Age	No. of Cigarettes	Delay (hours)
L. H. T.	21	3	3·5
,, ...	,,	3	2·0
,, ...	,,	1	Nil
E. M. V. W.	26	3	3·5
,, ...	,,	1	1·75
J. H. B.	51	1	3·25
T. H. C. L.	21	2	3·0
J. R. W. G.	19	2	3·25
G. B. P.	19	3	Nil

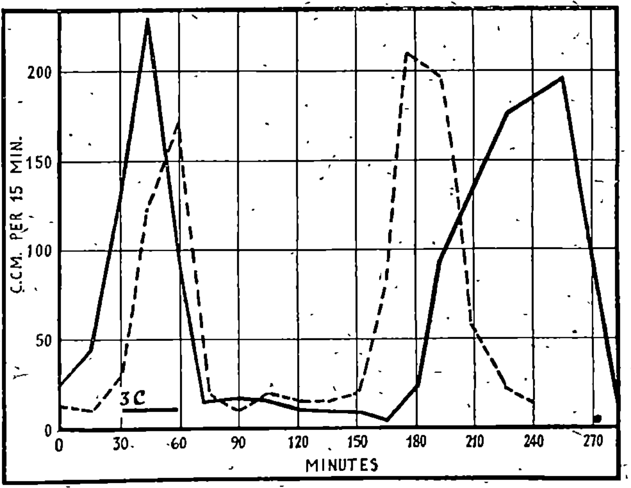

FIG. 4.—Similar experiments to that in Fig. 3, on subject L. H. T. The solid line is an experiment carried out smoking 3 cigarettes when L. H. T. was not otherwise smoking. The broken line is an experiment carried out also with 3 cigarettes when he was smoking 12 to 15 a day.

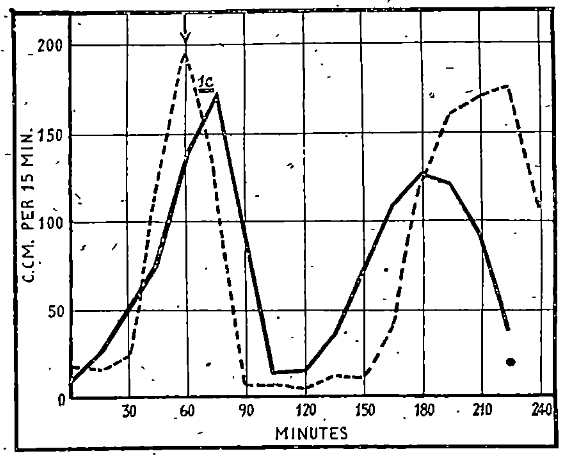

FIG. 5.—Similar experiments to those in Figs. 3 and 4. The broken line is an experiment in which 0.5 mg. nicotine (base) was injected intravenously at the arrow 60 min. after drinking the water. The solid line shows the effect of smoking one cigarette in the same subject.

Two experiments on L. H. T. afford further evidence that the antidiuretic effect is less when tolerance is established. These experiments are shown in Fig. 4. The first was done when L. H. T. had just finished a period of training for rowing, and had not been smoking; the delay was 3.5 hours. The second experiment was done seven months later, when L. H. T. was smoking 12 to 15 cigarettes a day; the delay was only 2 hours.

Intravenous Injection of Nicotine

In view of the large dose of nicotine required to produce the antidiuretic effect in the rat, it was surprising that smoking should exert an antidiuretic effect if this was due to the nicotine, as the amount of nicotine in the smoke seemed far too small. Some experiments were then carried out to determine whether small doses of nicotine would exert an antidiuretic action in human subjects. The nicotine was injected intravenously as acid tartrate when a diuresis was beginning. The effect of 1 mg. nicotine (base) in R. P. M. is shown in Fig. 6; the period of inhibition between the two peaks was 2.75 hours. In R. P. M. the injection of 0.5 mg. nicotine (base) had no antidiuretic effect. In E. M. V. W., however, the injection of 0.5 mg. nicotine (base) had an antidiuretic action such that the period between the two peaks was 2.75 hours (see Fig. 5). Now, as Fig. 5 shows, in this subject the smoking of one cigarette produced an antidiuretic action lasting 1.75 hours, so that the effect of one cigarette was rather less than that of 0.5 mg. nicotine (base).

Amount of Nicotine in Cigarette Smoke

Is there so much nicotine as this in the smoke of one cigarette? Schnedorf and Ivy (1939) have stated that one cigarette of the type they used yielded, in smoke taken in, about 0.2 mg. With the help of Mr. H. W. Ling we have determined the amount of nicotine which a smoker receives from British cigarettes. We connected a glass cigarette-holder to a long U-tube immersed in cold water. The other end of the U-tube was connected to a filter pump by a T-piece with one limb open to the air. When the filter pump was turned on gently, air was sucked in through the open limb of the T-piece. When this limb was closed, the air was sucked in through the cigarette-holder. We put a cigarette in the holder, lighted it, and, by alternately closing and opening the side limb of the T-piece, sucked some of the smoke into the U-tube and allowed part of it to escape into the air, imitating as closely as possible the ordinary smoking of a cigarette. The nicotine in the smoke was condensed in the U-tube. As a rule we "smoked" 10 cigarettes in the apparatus in succession. We then washed out the U-tube with ether, evaporated off the ether, and dissolved the residue with a little alcohol and 1% tartaric acid. As a rule the residue from 10 cigarettes (about 60 mg.) was collected in 10 c.cm. This solution was then estimated by comparing it with a known solution of nicotine acid tartrate for its pressor effect on the blood pressure of a spinal cat prepared by Dale's method (Burn, 1928). One estimation on 10 cigarettes gave the result that the smoke of one cigarette contained more than 0.66 mg. but less than 0.75 mg. nicotine (base). Estimations made on different batches of Gold Flake and Player's cigarettes gave figures varying between 0.6 mg. and 0.75 mg. nicotine (base) in the smoke of one cigarette. We observed no difference between the brands.

Now if 0.6 to 0.7 mg. nicotine enters the mouth of a smoker, not all of it will enter the blood. A certain proportion will do so, however, depending for its amount on how much the smoker inhales. When the smoker inhales, probably about 0.3 to 0.4 mg. reaches the alveoli of the lungs, from which it must be rapidly absorbed. This conclusion accounts very well for the observation on R. P. M. and E. M. V. W. In R. P. M. neither the intravenous injection of 0.5 mg. nicotine (base) nor the smoking of one cigarette had any antidiuretic effect. In E. M. V. W. the intravenous injection of 0.5 mg. nicotine (base) had an antidiuretic effect lasting 2.75 hours, and the smoking of one cigarette an effect lasting 1.75 hours.

Amount of Posterior Lobe Hormone Liberated

The antidiuretic action of nicotine depends on the pituitary body, and almost certainly, as Mary Pickford proved for acetylcholine, on the posterior lobe. Presumably the nicotine stimulates the supra-optic nucleus and adjacent nuclei, which, like it, send nerve fibres to the posterior lobe. When impulses arrive in the posterior lobe the antidiuretic hormone is released. What amount of hormone, in terms of the ordinary pituitary (posterior lobe) extract, is released when nicotine is injected? The ordinary posterior lobe extract is measured in units, the official strength being 10 units per c.cm. An attempt was made in subject R. P. M. to imitate the effect of 1 mg. nicotine (base) injected intravenously, as shown in Fig. 6, by injecting posterior lobe extract also by the intravenous route.

Posterior lobe extract was first injected in a dose of 0.05 unit. The antidiuretic effect, shown at B in Fig. 6, was shorter than that of 1 mg. nicotine (base) by 30 to 45 minutes. In the next experiment twice this dose was used—0.1 unit—but it produced the same effect. These results indicated that when posterior lobe extract was given intravenously the duration of the effect was not proportional to the size of the dose, but probably depended on the rate of destruction of the hormone. This was supported by the fact that when two doses, each of 0.05 unit, were given at an interval of 45 minutes the antidiuretic effect was much more like the nicotine effect, being in fact slightly greater. Thus the results indicated that an intravenous dose of nicotine does not exert a single momentary stimulus to the posterior lobe, but rather a stimulus which persists for 30 to 45 minutes.

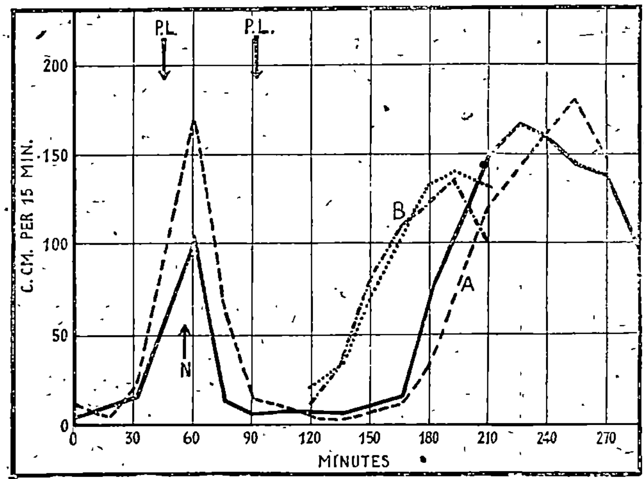

FIG. 6.—The solid line is an experiment in which 1 mg. nicotine (base) was injected intravenously into R. P. M. at arrow N. The broken line A is an experiment in which 0.05 unit posterior lobe extract was injected twice at an interval of 45 min. at arrows P.L. The lines at B are experiments in which (*a*) 0.05 unit and (*b*) 0.1 unit were each injected once.

Discussion

Although the effect of smoking in causing a rise of blood pressure has been known since 1907 (Hesse), that it does so cannot yet be said to be a matter of common knowledge. Recent observations by Roth, McDonald, and Sheard (1944) provide fresh evidence on the point, and also demonstrate the fall of skin temperature due to the vasoconstriction of the skin which occurs. The rise of blood pressure, of pulse rate, and of vasoconstriction in the skin are all the result of the stimulation by nicotine of sympathetic ganglion cells. The observations recorded in this paper indicate that it is not only the nerve cells of the sympathetic ganglia which are stimulated by nicotine but that nuclei in the hypothalamus are also stimulated, as a result of which the hormone of the posterior lobe of the pituitary is liberated in the blood. The effect was accompanied in several of the observations by symptoms regarded as toxic effects of nicotine, such as vertigo, nausea, and even vomiting. These effects were not always present, and there is no doubt that the antidiuretic action is observed in their absence.

If smoking causes secretion of the antidiuretic hormone it seems reasonable to suppose that the other hormones of the posterior lobe, such as the oxytocic hormone, are also liberated. If this occurs, smoking should accelerate labour.

Many believe that there is a connexion between smoking and gastric ulcer, and since Dodds *et al.* (1934) have shown that the injection of posterior lobe extract into rabbits causes gastric ulcer, it might appear that our experiments suggest the mechanism of the connexion. This is very doubtful; large amounts of posterior lobe extract are needed to produce ulcers, and the effect of pharmacopoeial doses of posterior lobe extract in man is to diminish gastric acidity, not to increase it. This we have observed here, in confirmation of other workers. Our experiments do, however, raise the question whether those with impaired kidney function should be allowed to smoke.

Summary

Nicotine exerts an antidiuretic effect in the rat. This effect does not occur if the pituitary body is removed.

Smoking exerts an antidiuretic effect in man. In a sensitive subject one cigarette will inhibit diuresis for 2 to 3 hours.

The same antidiuretic effect is produced in man by the injection of nicotine intravenously in an amount approximately equal to the amount absorbed from one cigarette.

It is probable that the nicotine absorbed from cigarette smoke stimulates the supra-optic nucleus of the hypothalamus and causes a discharge of the hormone from the posterior lobe of the pituitary gland.

Our thanks are due to those already mentioned in the paper, and also to Mr. E. M. Vaughan Williams and Mr. R. P. Michael for their care in making observations.

ENFORCED LEISURE

A STUDY OF THE ACTIVITIES OF OFFICER PRISONERS OF WAR

BY

A. R. DEARLOVE, M.B., B.S.Lond., B.Sc.Witwatersrand
Captain, R.A.M.C.

Recent articles and correspondence in the medical press on prisoner-of-war mentality have naturally caused considerable discussion in P.O.W. camps. Whether rehabilitation on a large scale will be necessary or not is difficult for the individual to say. Nevertheless some observations on how the P.O.W. spends his time may be of general interest. In this paper an attempt is made not to produce an average individual but to assess what contribution the average prisoner makes to the life of the camp.

Oflag VII/B was originally formed as a camp for young officers. Its strength varies, but in the period under review is about 1,700, of whom 110 are Canadians, 117 are Australians, 87 are New Zealanders, and the rest are from the British Isles. There is a sprinkling of officers from other parts of the Empire. One is justified in regarding it as presenting a fair cross-section of the educated classes of the Empire. The living conditions, as regards accommodation, are fairly similar, while the food is completely standardized. Facilities for recreation, study, sport, etc., are available in exactly the same measure to everybody. The extent to which these facilities are exploited naturally depends on the individual.

Despite the limitations of the questionary form of investigation, it was chosen as being the only one practicable in the peculiar circumstances of captivity. A questionary covering all possible forms of camp activity was drawn up. This was issued to a number of patients in hospital, who were asked to allocate times on the basis of an average day to the various activities. The data thus collected proved interesting, and it was decided to extend the investigation to get a fair sample of the camp as a whole. The questionary was issued to various people, with a request that in each case every member of the mess or room should answer it. In some cases the return was 100%, in others there were one or two men who, for various reasons, refused to co-operate. Nevertheless I think that the return represents a fair cross-section of the camp.

It will be observed that no name is asked for; nevertheless, by inquiry it was generally possible to trace individuals when any point required clarifying. One objection raised was, What is the difference between "study" and "serious reading" or between "light" and "serious" reading? To me it seems purely an individual distinction. Most people know what they are trying to study and they also have their own standards of serious and light reading, and I have accepted these standards.

Form of Questionary

Country (or Dominion) of Origin: *Age:*
Previous Occupation:
Length of Captivity: *Educationa Standard:*
Average Day:
I. Camp official (administrative, parcel education, medical, sports, etc.) .... hrs.
II. Activity for benefit of community (non-official): e.g., work on wood pile, gardening, tutoring, block cooks, Toc H nursing, voluntary massage, or any other altruistic activity .... hrs.
III. Study: (*a*) Prescribed course for examination .... hrs.
(*b*) Language—which? .... hrs. } .... hrs.
(*c*) General study .... hrs.
IV. Handicrafts: Model-making, woodwork, tinsmithing, knitting, etc. .... hrs.
V. Art: Painting, drawing, sketching, modelling, etc. .... hrs.
VI. Music: (*a*) As performer. What type of instrument? .... hrs. } .... hrs.
(*b*) Listening .... hrs.
VII. Writing: (*a*) Books or articles for possible publication .... hrs. } .... hrs.
(*b*) Diary or scrapbook for own amusement .... hrs.
VIII. Dramatics: (*a*) Actor .... hrs. } .... hrs.
(*b*) Producer, stage hand, scenery designer, etc. .... hrs.
IX. Reading: (*a*) Serious .... hrs. } .... hrs.
(*b*) Light .... hrs.
X. Sport or exercise: (*a*) Active .... hrs. } .... hrs.
(*b*) Spectator .... hrs.
XI. Indoor games, chess, or cards for amusement or nominal stakes .... hrs.
XII. Gambling .... hrs.
XIII. Serious discussion .... hrs.
XIV. Aimless gossip (war, reminiscences, local gossip) .... hrs.
XV. Sleeping and eating .... hrs.
XVI. Time spent on household fatigues .... hrs.
XVII. Hobbies: bird-watching, flowers, collecting (types of cigarettes, etc.) .... hrs.
XVIII. Do you attend general interest lectures?
XIX. Do you work to a time-table?
XX. Have you improved, or not, physically? How? Since when?
XXI. Have you improved, or not, mentally, especially with regard to interest, concentration, and memory?

Discussion of Table I

The first two groups cover most of the actual work required for the running of the camp. The average time of 35 minutes per head for camp administration may appear high to an efficiency expert. 100 forms recorded some kind of activity. Three claimed to work 7 hours and one 6 hours a day, but the majority worked 1/2 to 1 hour a day. (Frequency Diagram 1.)

In Group II 45 minutes also appears high. Nevertheless, in a P.O.W. camp there is a considerable amount of reciprocal service. The massage department in the hospital is entirely staffed by volunteers, all of whom have learned massage in captivity. Block cooking is also done by volunteers; while, apart from the teaching organization, there is an enormous amount of private tuition.

III. *Study.*—The overall averages in this group are misleading (see Frequency Diagrams 3, 4, and 5). (*a*) *Courses:*—29% claim to be following courses of study, and on an average they study 3 hours 46 minutes a day. One claims 11 hours, one 9 hours a day. Although these figures seem high they are not incredible. From reveille onward the study rooms are continuously occupied. (*b*) *Languages:*—Most prisoners have studied some language—usually German—at one stage or another in their captivity. In the present sample 31% study, on an average, 1 hour 32 minutes daily. German and French head the list; Russian is popular; every European language has its students. Less well-known languages, such as Gaelic, Afrikaans, Urdu, Malayan, Arabic, receive attention. (*c*) *General study:*—51% register time spent on general study. This represents 1 hour 47 minutes per head, as contrasted with 3 hours 46 minutes in the group pursuing courses of study. It suggests that even in captivity study must have a purpose. The simple pursuit of knowledge is not enough.

IV. *Handicrafts.*—17% are occupied on hand work of some description. Towards the end of winter, knitting was fashionable. Tapestry, needlework, weaving, tailoring, watch-making, model-making, all occupy a certain amount of time, but the total time and the time per head are relatively small.

V. *Art.*—11% devote 32 to 35 hours to drawing, sketching, or painting. This represents about 57 minutes per head.

FREQUENCY DIAGRAM 1.—Group I, Camp Administration: 100 record some form of activity; 200 record *nil*. (In all these diagrams the "nil" column has been omitted owing to lack of space.)

FREQUENCY DIAGRAM 2.—Group II, Altruistic Activities: 135 record activity; 165 record *nil*.

FREQUENCY DIAGRAM 3.—Group III, Study; (*a*), group taking prescribed course: 87 students.

FREQUENCY DIAGRAM 4.—Group III, Study; (*b*), group studying languages: 93 students.

FREQUENCY DIAGRAM 5.—Group III, Study; (*c*), general study group: 153 students.

FREQUENCY DIAGRAM 6.—Group IV, Handicrafts: 51 occupied: 249 *nil*. * Time claimed, less than 1/4 hour per day.

FREQUENCY DIAGRAM 7.—Group V, Art: 33 occupied; 267 *nil*. * Time claimed, less than 1/4 hour per day.

FREQUENCY DIAGRAM 8.—Group VI, Music; (*a*), Performer: 13 performers; 287 *nil*. * Less than 1/4 hour per day.

FREQUENCY DIAGRAM 9.—Group VI, Music; (*b*), Listener: 132 listeners; 168 *nil*. * Less than 1/4 hour per day.

FREQUENCY DIAGRAM 10.—Group VIII, Dramatics: 9 actors, etc.; 291 *nil*. * Less than 1/4 hour per day.

VI. *Music.*—(*a*) *Performers:*—There are enough musicians in the camp to provide music for all shows and, in addition, to stage a music festival covering symphonic, choral, orchestral, light orchestral, chamber music, and dance band programmes. This, however, is the work of a relatively small number. In the present sample 13 average 1 hour 8 minutes a day, but this figure includes one man who spends 4 hours a day orchestrating music for the various instruments in the camp. (*b*) *Listeners:*—Apart from the musicians the camp has an excellent record library and a fair number of gramophones. 132 people devote, on an average, 32 minutes a day to music—i.e., about two evenings a week.

VII. *Writing.*—(*a*) The number of potential or active writers at 12.3% is probably high. The actual "market" is small, and consists of two monthly camp magazines. (*b*) The number of people keeping diaries—25.3%—also seems high considering the unexciting round of ordinary camp life. However, it is a personal and unexacting form of self-expression, and is one of the few open to a prisoner of war.

VIII. *Dramatics.*—Only 3% claimed to be in any way occupied with the stage. The acting fraternity tend to live together, and it is possible that they are not fairly represented in the survey. Nevertheless, the plays staged in the camp are produced by a small number of good actors—so good, indeed, that the tyro has very little chance. (It is interesting that the most spectacular features of camp life—viz., the Arts and Crafts Exhibition and the theatre shows—are, basically, the work of very few and do not in any degree represent the industry and talent of the camp as a whole.)

IX. *Reading.*—Everybody reads to a greater or lesser extent. The only negative returns in this category were from men who spend several hours a day in study.

X. *Sport.*—Similarly, everyone takes some form of exercise. The limiting factor in some cases is not so much lack of energy or equipment as lack of space, and every sports field is used continuously by fresh teams throughout the hours of daylight.

XI. *Cards and Indoor Games.*—These are not as popular as one might have expected. However, the season (early summer) may to some extent account for this.

XII. *Gambling.*—10% are occupied in games of chance. The camp moralists are inclined to disapprove. Nevertheless it provides a harmless outlet for a variety of captivity and social impulses. The craving for excitement can be satisfied to a certain extent, and the acquisitive instinct can sometimes be gratified without the community being in any way affected.

XIII. *Serious Discussion.*—I consider an average of 24 minutes per head a modest understatement.

XIV. *Aimless Gossip.*—An average of 1 hour 16 minutes per head is probably fair. Normally, there are not enough rumours or camp trivialities to occupy very much more time than this unless one gravitates from group to group. So, for lack of subject-matter, an aimless gossip quite often becomes a serious discussion.

XV and XVI.—Rooms are divided into messes, numbering from 2 to 8 members. Members in turn prepare food and do the fatigues incidental to eating. Sleeping and eating are among the most important of camp activities.

XVII. *Hobbies.*—Naturally there is very little scope for this form of activity. Popular are bird-watching, butterfly-collecting, collecting various brands of cigarettes, coins (?), razor blades; designing homes, motor-cars, yachts. *Unaccounted Time.*—Roll calls occupy about 30 minutes a day. The remainder is taken up in various insignificant ways—" doing nothing," as one man expressed it. No allowance on the questionary was made for meditation. Two people claimed 4 hours a day under this heading.

XVIII. *General Interest Lectures.*—" Occasionally " and " Sometimes " were interpreted as affirmatives.

XIX. *Work to a Time-table.*—I had assumed that most prisoners would slip into some form of daily routine, and, as a matter of habit, stick to it. Apparently the majority do not.

XX.—In an endeavour to avoid the suggestion contained in the words " impaired " or " deteriorated " the question read, " Have you improved, or not, physically? " To my surprise a few admitted to actual physical improvement. 66.3% consider themselves unimpaired or are not certain about it. Of the impaired group the deterioration is expressed as " loss of weight," " no stamina," " teeth and eyes affected," " sinusitis," " asthma developed," " migraine started." In the last two instances I naturally tried to establish some connexion between captivity and the onset. In migraine I was unsuccessful, in that each of the patients had actually had migraine for some years, but the label had been attached only during captivity. Regarding asthma, several cases have developed since capture. Clinically, headache, sciatica, and rheumatism are fairly common, and are to a large extent, no doubt, somatic manifestations of mental strain. Whether competent psychological treatment would, in the circumstances, be successful is an academic matter, because such treatment is not available. In its absence, headache is described as probably due to sinusitis or eye strain and treated accordingly. The other conditions are treated symptomatically—not, unfortunately, with uniform success.

XXI.—It was rather difficult to assess answers, in that a number of replies confused " interest " with " interests," and so some of the men replied: " Memory and concentration worse. Interest wider and improved." In general, it appears that memory and concentration have suffered, while interest is erratic. A few regard their captivity as a total loss, while others, making a virtue of necessity, have used their leisure for broadening their interests. Naturally there is no strict line of demarcation between the physical and mental states, and replies expressing a deterioration in one often express a similar deterioration in the other.

Grouping by Length of Captivity

By way of contrast, and in order to provide a kind of chronological " Prisoners' Progress," replies have been subdivided into four groups—1-, 2-, 3-, and 4-year prisoners respectively. Of further interest is the origin of the groups. Groups 1 and 4 are chiefly from the British Isles, Group 2 is predominantly Canadian, and Group 3 predominantly Australian and New Zealand.

The following is an analysis of the sample summarized in Table I. The number in Group 1 is probably high in proportion to the total number of 1-year prisoners in the camp. The other groups are roughly in proportion.

Group 1	Number 26	Average age 28·8 years
„ 2	„ 36	„ „ 32·8 „
„ 3	„ 81	„ „ 30·3 „
„ 4	„ 157	„ „ 29·1

	24 h. 0 m.	24 h. 0 m.	24 h. 0 m.	24 h. 0 m.
XVIII. General interest lectures: Yes	31%	61%	58%	61%
XIX. Work to time-table: Yes	12%	22%	37%	29%
XX. Feeling physically impaired: Yes	15%	47%	40%	33%
XXI. Feeling psychologically impaired: Yes	19%	55%	41%	38%

Discussion of Table II

The similarity between Groups 3 and 4 may be due to two causes: (*a*) larger numbers in groups eliminate the swings in either direction owing to individuals recording high figures in a particular activity; (*b*) possibly, after two years, adjustment to captivity is fairly complete and a more or less stereotyped " average " routine is adopted.

Study.—It is remarkable how quickly first-year prisoners have got down to courses of study.

Music.—Several of the older prisoners have learned music in captivity, which probably accounts for the slight increase in time.

Writing.—The number writing diaries decreases after the first novelty wears off.

Physical Impairment.—In Group 1 this is due to temporary unfitness from wounds. The same applies to a few in Group 2, but, apart from that, there is no clinical difference between the groups. Nevertheless, this survey is, of course, purely subjective, and indicates what the individual thinks about his physical and mental state. The relatively low figures for the 4-year group may be due to three factors: (*a*) They represent a rather younger age group; (*b*) they show more complete mental adjustment; (*c*) possibly a matter of pride, and refusal to admit to impairment after a long spell in adverse circumstances.

Analysis of Effect according to Age

Finally, in order to determine the effect of age on the use of leisure and the mental attitude towards captivity, the sample has been divided into two groups—under 30 and over 30. A sharper contrast would naturally have been provided by an under 30 and over 40 comparison. However, the number of prisoners over 40 is too small to permit this. (See Table III.)

Group I: Under 30 ..	Number 179 ..	Average age 26·4 years
„ II: Over 30 ..	„ 121 ..	„ „ 35·8

Discussion of Table III

The older age group is, not unexpectedly, occupied to a greater extent on administrative and altruistic activities. Comparison of the two groups with regard to study is interesting, because of (*a*) the large number of men over 30 who are following courses, and (*b*) the amount of time devoted by this group to study. The older group appears to be slightly ahead on art, music, writing, and dramatics. The figures for light and serious reading are what one would

TABLE III

XX. Feeling physically impaired: Yes	32%	39%
XXI. Feeling psychologically impaired: Yes	40%	41%

normally expect. Similarly, the amount of time spent by the younger group on sport is naturally rather higher. That the over 30 group should attend general interest lectures to a greater extent is unexpected; but that they should be more apt to work to a routine is natural. The older age group would feel that they had suffered deterioration physically to a greater extent than the younger. Under any circumstances physical activity would tend to be less over the age of 30. With regard to mental deterioration the two groups are almost equal.

General Conclusions

Under wartime conditions most people are forced to "waste time" in the sense that individual studies and careers are interrupted. The prisoner of war, in this respect, is no worse off than anyone else, except that he has leisure which, although unlimited in time, yet in space is very strictly limited. He utilizes this in activities which may be roughly grouped under three headings.

(*a*) *Work.*—Official and altruistic activities, study and fatigues amounting to about 5 hours a day per head.

(*b*) *Vegetative and—Predominantly—Time-consuming Activities.*—These are represented by: sleeping and eating, gossip, card-playing, and unaccounted time, amounting to about 14½ hours a day per head.

(*c*) *Creative and Recreational.*—Art, music, handicrafts, writing, dramatics, reading, hobbies, sport, and lectures, amounting to about 4½ hours a day.

From this it would be rash to draw general conclusions, but, under P.O.W. conditions, I doubt whether the time spent on creative and recreational activities could be much increased even with unlimited facilities. Apart from reading and sport, the average English education makes no provision for leisure. (Judging from camp activities, the Australian and New Zealand systems follow the English fairly closely.) The North American education is worse in this respect. The 2-year group seem to reflect a high level of specialized education in that there are more university degrees than in the other groups, yet the average time spent in Category C is only 2½ hours per head.

My general impression is that the physical and mental well-being of the P.O.W. largely depends on his daily activities and, of course, conversely. This is rather strikingly illustrated by the case of an ex-schoolmaster who worked conscientiously 6 hours a day for 3 years, passed two difficult exams., and then quite suddenly developed sciatica and polyneuritis, which incapacitated him for further study. Few of the replies were as clear-cut as this. Nevertheless, in replies which devoted most time to vegetative and time-consuming pursuits, there was a greater tendency to admit physical and mental impairment or to complain of symptoms for which an organic basis could not be found. This may represent a "P.O.W. neurosis" similar to the commoner "war neurosis," which, according to Gillespie, arises at a superficial level and will presumably disappear when the conditions causing it are removed.

It is a pleasure to acknowledge the work done by the various branches of the Red Cross and other charitable organizations in providing the necessary facilities to enable P.O.W.s to lead a fairly normal life in captivity. I am indebted to Major G. Hadley, R.A.M.C., and Major E. Parker, R.E., for help and criticism, and to numerous officers in camp for assistance.

SUBSTANCES USED IN TREATMENT OF PEDICULOSIS CAPITIS

THEIR RELATIVE VALUE

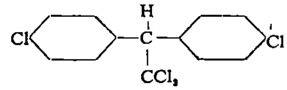
BY

ELIZABETH B. S. SCOBBIE, M.B., Ch.B., D.C.H.

Department of Child Health, King's College, Durham University, and the Royal Victoria Infirmary, Newcastle-upon-Tyne

The objects of the investigations here described were to test the efficiency of substances which have recently been recommended for the destruction of head lice and their nits, and to compare these with older methods. The substances were first brought to trial by laboratory tests in which their insecticidal and ovicidal actions were observed under the conditions of controlled bench experiments. They were then tried by direct observation of their effects on subjects kept under controlled clinical conditions. Some of the substances were tried by a third method of attempting infestation in volunteers whose heads had been treated with the test substance.

The newer substances on trial were: (1) 50% lethane 384 special in a white oil (Busvine and Buxton, 1942); (2) 25% technical lauryl thiocyanate in a white oil (Busvine and Buxton, 1942); (3) ascabiol (new formula), a non-irritating preparation of benzyl benzoate emulsion (Blackstock, 1944); (4) emulsion of D.D.T.: 4 parts D.D.T. in (30 parts heavy solevent naphtha +10 parts "amoa A.S.X."). Diluted with water to give 2% D.D.T. This D.D.T. emulsion was supplied by the Ministry of Health for experimental purposes.



D.D.T. (dichlor-diphenyl-trichlorethane)

The older substances tried for the purpose of comparison were: carbolic acid solution (1 in 40 and 1 in 60), "derbac" soap, 20% solution of dettol, concentrated infusion of quassia, quassia mixture (Jörgensen, 1940), 12.5% formalin soap mixture *B.P.C.* (Ministry of Health Memo., 1940), spirit soap, formalin, 0.1% mercuric chloride in spirit, 0.1% aqueous mercuric chloride, methylated spirits, 3 to 1 mixture of methylated spirits and water, 2% lysol, 2% β-naphthol in spirit, ol. abietis in spirit, oil of cedarwood, oil of citronella, oil of lemon-grass, oil of sassafras, oil of turpentine, paraffin oil, and 5% tar oil.

Laboratory Tests

Laboratory tests are carried out under arranged experimental environments which are to that extent artificial, but they are useful as a preliminary to clinical tests because they demonstrate which of the test substances have no lethal action. These substances can then be discarded as useless and requiring no further clinical test. Laboratory tests are useful also in indicating the manner in which the substances kill the lice. From this the most suitable methods of their application to the hair and scalp can be deduced. For example, a substance may be shown to act through its vapour, and so the best method of applying it (apart from elaborate mechanical devices: Lebailly, 1937) will be by soaking the head with the substance and covering it with a rubber cap to keep the maximum amount of the lethal vapour in contact with the hair. Other substances act directly on the lice, presumably entering their bodies through their external chitinous skeletons. The effect of each insecticide on the nit (or egg) has also to be determined, because if one application of any substance is to be effective it must kill all the nits as well as all the lice. If it does not kill all the nits, larvae will hatch out during 6 to 8 days after treatment, and the state of infestation will continue unless the insecticide persists on the hair and scalp over this period and kills the larvae as they hatch out.

The following is a summary of the laboratory tests used and the results obtained. The lice were taken from infested heads or were bred for the purpose :

Experiment I

The lice were placed on a tuft of cut hair, which was then wrapped in a piece of cotton material soaked in the insecticide and left in position for a period of from 1/2 to 1 hour. The lice were then removed to an observation glass and their behaviour watched for from 4 to 6 hours. It was found necessary to observe them for this length of time to exclude the possibility of sham death or of stupefaction with later survival. This precaution was observed in all the laboratory experiments. The number of lice used for each experiment varied from 5 to 14. According to their results the drugs were divided into three groups: (A) effective—all lice being killed; (B) probably effective—most lice killed, some moribund; (C) ineffective—majority of lice surviving.

The following substances proved to be effective insecticides under the conditions of this experiment and were placed in Group A: D.D.T. emulsion, lethane, lauryl thiocyanate, 2% lysol, sassafras oil, turpentine, methylated spirits, quassia mixture, ol. abietis in spirit, 0.1% mercuric chloride in spirit, 2% β-naphthol in spirit, paraffin oil, and formalin. Less conclusive results were obtained from the use of carbolic acid solution (1 in 40), benzyl benzoate emulsion, 20% dettol, and spirit soap. These were placed in Group B. The remainder of the substances tested were placed in Group C as they proved ineffective. These were: 0.1% mercuric chloride in water, concentrated infusion of quassia, 12.5% formalin soap mixture, oils of cedarwood, lemon grass, and citronella, and 5% tar oil.

Experiment II

Three to five lice on a tuft of hair, and a small watch-glass containing the insecticide to be tested, were placed separately in a covered glass vessel 3½ in. in diameter. The vessel was left at a temperature of 20 to 23° C. for 1 to 1½ hours, and no contact between the lice and insecticide was allowed to take place. The vapours of methylated spirits (and any insecticide containing methylated spirits) and tar oil were effective as insecticides. Some drugs were found to stupefy the lice, which on their removal to fresh air recovered at varying intervals up to 4 hours, even though they looked quite dead when first removed. Carbolic acid (1 in 40), D.D.T. emulsion, 2% lysol, lethane, and oil of sassafras acted in this way. The vapours of lauryl thiocyanate, oil of lemon-grass, and paraffin oil had no effect on the lice.

Experiment III

A tuft of hair was dipped in the insecticide, the excess of which was then dabbed off on a dry cloth. Two or three lice were then applied to the hair and their behaviour observed for 15 minutes.

Of the insecticides tested in this way—lethane, lauryl thiocyanate, sassafras oil, methylated spirits, paraffin, 0.1% mercuric chloride, 1 in 40 carbolic acid, and D.D.T.—lethane alone showed any effect. After 2 to 4 minutes the lice remained quite immobile although intestinal peristalsis continued for 1 to 2 minutes longer. Removal of the lice at this stage was not followed by recovery. This experiment was repeated 8 times with similar results. The amount of test substance left on the hair when it is treated in this way will vary with the viscosity of the substance, and the test is to that extent inaccurate. It is also possible that certain drugs may have a delayed action, and had the lice been observed for a period longer than 15 minutes after exposure to the treated hairs other insecticides would have been found effective. But this experiment does demonstrate that lethane is effective in very small quantities and that it has a rapid action.

Experiment IV

In this experiment the effects of various substances on nits were determined. The nits were obtained from two sources: (1) from the heads of children, the hair with the nit attached being pulled out by the root or cut close to the scalp; (2) from lice kept in a breeding-box. In every experiment untreated nits from the same source as those used in the test were set aside and incubated to act as controls. The nits were immersed for 5 minutes in the insecticides at room temperature and were then transferred to the incubator. From the percentage hatch of the control group and the percentage hatch after treatment, the percentage reduction of hatch was calculated, taking the hatch of the control as 100%. The results are given in Table I.

TABLE I.—*Effects on Nits of Immersion in Insecticide (Experiment IV)*

Treatment	Treated Nits			Control Nits			% Reduction of Hatch
	No.	Hatched	% Hatch	No.	Hatched	% Hatch	
D.D.T. emulsion ..	10	3	30	9	7	78	62*
Lethane	15	5	33	8	6	75	56*
Lauryl thiocyanate	6	6	100	8	6	75	0

2% lysol	12	0	0	12	7	58	100*

* Statistically significant in that the difference is greater than twice the standard error.

Summary of Results of Laboratory Tests

From the results of these experiments it is seen that many substances are lethal to the louse, but the insecticide with the quickest and most reliable action is lethane. In Experiment III the rapid action of lethane is very striking as compared with other insecticides. Methylated spirits and tar oil seem to act by their vapours. Many insecticides dissolved in or mixed with methylated spirits owe their insecticidal action to the spirits. Treatment with these agents should be carried out in such a way that the vapour has a chance to take effect, preferably by the use of a rubber cap. From the results of Experiment IV, lysol and carbolic acid solution appear to be the most effective ovicides. D.D.T. emulsion and lethane are moderately effective ovicides, but the other substances tested in this way are unreliable. The ovicidal action of D.D.T. emulsion is probably due to the other ingredients in the emulsion (Busvine, personal communication).

Controlled Clinical Tests

The object of these experiments is to test the lethal action of various drugs on the louse and on the nit, under conditions which are natural but controlled, so far as is possible, to allow comparisons to be drawn between the different reagents. This method of investigation gives results which are of more value than those obtained by laboratory experiments because the drugs are tested under natural conditions.

The method used to determine the lethal action on the louse was the application of the test substance to a head in which a known number of lice were present. The head was carefully toothcombed 12 to 18 hours after treatment and the condition of the lice noted—dead, moribund, or apparently healthy. To determine the lethal action of the test substance on the nits a comparison was made between the hatching rates of the nits before and after treatment in the following way:

Before treatment was started, hairs with nits attached were pulled out by the roots or cut close to the scalp. Each nit was examined with a hand lens, and if the operculum was broken off or the nit appeared empty it was discarded. Ten to twenty full nits with intact opercula were placed in a container in the incubator to determine the hatching rate before treatment was given. These acted as controls. In exactly the same manner 10 to 20 full nits were removed 24 hours after the application of the substance under trial, and they were incubated under the same conditions as the control nits. Both lots of nits were examined 10 days after they were put in the incubator. By counting the number of full and empty nits the hatching rate was determined. From these figures the percentage reduction of hatch was calculated and a comparison of the effects of the different substances on the nits could then be made. Further control of the drug's ovicidal action was made by daily toothcombing for 10 days and by examination of the combing with a hand lens. The results obtained in these experiments are shown in Table II.

Discussion

Although the number of cases used for each controlled clinical experiment varies and in some instances is small the results are clear enough to enable one to draw certain conclusions, which further observations of the field-trial type will confirm or refute.

First, with regard to the *lethal action on the louse* the following substances have proved effective: lethane, 100 cases; 2% lysol, 6 cases; oil of sassafras, 6 cases; paraffin oil, 4 cases; 5% tar in oil, 4 cases; methylated spirits, 6 cases; ascabiol, 10 cases; D.D.T., 10 cases. Derbac soap and dettol solution were included in the experiments because so many mothers were found to have used them on their children. Both are quite ineffective. The formalin soap mixture (M.O.H. Memo., 1940) is also unreliable. Carbolic solution was successful in some but not all cases, and lauryl thiocyanate was unsatisfactory in the 6 cases in which it was used.

Secondly, the *ovicidal action* of these substances is of interest. Judged by the purely experimental results of their effect on the hatching rate of the nits, lysol and methylated spirits have the most efficient lethal action. Ascabiol, sassafras oil, carbolic acid, and turpentine come next in order of efficiency. If the substances are classed according to the results of toothcombing a different order is obtained. This is due to the property of lethane, and particularly of D.D.T., of persisting on the hair and scalp and killing the larvae as they hatch out (see below). Ascabiol, although it produced fairly satisfactory results, did not "have a solvent action on the cement of the nit," nor was "simple washing with soap and water sufficient to remove all remaining nits," as claimed by Blackstock (1944).

TABLE II.—*Results of Controlled Clinical Experiments*

Treatment	Method	Effect on Lice	Effect on Nits			Control Nits			% Reduction of Hatch	Results of Toothcombing
			No. of Nits	No. which Hatched	% Hatch	No.	No. which Hatched	% Hatch		
Ascabiol	Approx. 2 oz. applied with brush to scalp and hair	All killed	20	2	10	20	19	95	89*	Very occasional larvae
1 in 60 carbolic acid ..	Wet hair thoroughly; apply compress 8 hours	Not all dead	10	3	30	10	10	100	70*	Larvae
Derbac soap	According to directions	No effect	26	16	61	22	12	55	0	Abundant larvae
D.D.T. emulsion ..	4–5 teaspoonfuls applied to scalp and rubbed in	All killed	20	15	75	15	14	93	19	Nil
1 in 20 dettol solution	Wet hair thoroughly; compress applied 6 hours	No effect	12	5	58	14	9	64	9	Abundant larvae
Formalin soap mixture	According to directions	Not all killed	21	11	52	13	9	69	25	Several larvae
Lauryl thiocyanate ..	2–3 dr. by spray or pipette; applied to scalp	„	20	11	55	20	16	80	31	Larvae
Lethane	„ „	All killed	20	6	30	20	12	60	50*	A few larvae
2% lysol	Wet hair thoroughly; compress applied 8 hours	„	9	0	0	10	9	90	100*	„ „
75% methylated spirits	„ „	„	13	0	0	17	9	47	100*	Very few larvae
Paraffin oil	„ „	„	8	3	37	7	5	71	48	A few larvae
Oil of sassafras ..	„ „	„	31	4	13	27	25	93	86*	Occasional larvae
5% tar in oil	2 oz. applied to scalp and hair	„	7	2	30	5	3	60	50	A very few larvae
Turpentine	2–3 dr. applied to scalp; rubbed in	Not all killed	10	2	20	11	7	64	69*	Several larvae

* Statistically significant in that the difference is greater than twice the standard error.

Its results were obtained by its ovicidal action, 80 to 90% of the nits being killed. With careful toothcombing, a greater number of nits are removed after treatment with ascabiol than with other agents, such as methylated spirits and carbolic acid. Ascabiol appears to have a slight lubricant effect, but in no instance was it found to be an "easy method of freeing the scalp from nits."

The relative inefficacy of the other substances as ovicides should be sufficient to remove them from the extensive list of therapeutic agents which have long been advocated for the treatment of pediculosis.

The Protective Action

The third method was that of attempting infestation of heads of volunteers after treatment with the test substances. Methylated spirits, lysol, ascabiol, D.D.T. emulsion, and lethane hair-oil were tested in this manner. Of these substances, only D.D.T. and lethane persisted in the hair and were able to continue their lethal action for more than 24 hours. Three or four lice were applied to the hair 24 hours after treatment and the head was toothcombed the following day. Recovery of lice was taken as evidence that the test substance did not possess any protective properties. Recovery of dead lice or failure of recovery after careful toothcombing was taken as evidence of protection. When protection occurred, healthy lice were again applied and the head toothcombed the following day. This was continued until living lice were recovered.

One application of lethane was found to protect the head for from 4 to 6 days in 6 subjects, the length of protection varying from case to case according to the extent to which the oil was rubbed off on the pillow and also possibly to slight difference of technique. Washing of the hair removes the lethane and thus destroys its protective action. One application of D.D.T. emulsion protects the head for from 14 to 18 days if the hair is not washed after treatment, and for from 11 to 15 days if washing is carried out. Eight cases treated with D.D.T. emulsion were tested in this way. In 4 cases the head was washed 1 to 3 days after D.D.T. emulsion had been applied.

The discrepancy between the relatively weak ovicidal action of lethane and D.D.T. and the results of toothcombing is explained by the persistence of these substances in the hair or on the scalp in an active state for 4 to 6 days and for 14 to 18 days respectively. Those nits that escape being killed give rise to larvae which stand a poor chance of survival, as they must come into contact with the insecticide on the hairs near the scalp and on the scalp itself when they go there to feed. This point emphasizes the importance of the method of applying the agent—viz., it should be rubbed into the scalp and the hair near the scalp, where the lice go to feed. The fact that in heads treated with lethane a few first-stage larvae often appear from the 5th to the 8th day, confirms the observation that its lethal action does not persist for more than 5 to 6 days. Every case so far treated with D.D.T. emulsion has been cured by one application. This result is to be expected, as the duration of protection with D.D.T. exceeds the incubation period of the nits (6 to 8 days).

Conclusions

The ideal substance for treating pediculosis is one which kills all the lice and all the nits immediately, or, failing that, one which kills all the lice immediately and which persists in the hair during the incubation period of the nits so that it kills off the larvae as they hatch out. No drug has been found which will kill all the nits in the hair on one application. It is difficult to apply a substance in sufficient concentration to affect every nit without damaging the scalp or adjacent skin. 2% lysol is the agent which is most effective on the nits, and in this concentration it is safe to use. Ascabiol, sassafras oil, and carbolic acid solution come next in order of efficiency, but in practice none of these ovicides gives a 100% kill.

Among the substances tested, the nearest approach to an ideal is D.D.T. emulsion, which kills all the lice and persists in the hair long enough to kill all the larvae. Lethane has a similar action but does not persist so long, and some larvae which hatch towards the end of the first week after treatment may survive. D.D.T. emulsion has other advantages over lethane hair-oil. Its smell, which is not unpleasant, quickly disappears and the hair looks natural after treatment. If desired, the hair can be washed, as D.D.T. is insoluble in water, and the washing does not appreciably affect its action. Lethane has an unpleasant, persistent smell; it gives the hair a greasy appearance, and the head must not be washed for 10 days. No toxic reaction or irritation of the scalp or skin has been noted after the use of lethane hair-oil or of D.D.T. emulsion.

Summary

A series of laboratory and clinical tests is described in which an attempt is made to compare the efficiency of a number of "cures" for pediculosis capitis. Some of the substances in common use are shown to be either ineffective or definitely inferior as insecticides and as ovicides. Any success obtained by their use can be ascribed largely to the mechanical removal of the lice by the careful toothcombing which is usually an important part of the treatment.

D.D.T. emulsion and lethane hair-oil stand out as the two insecticides of value in the treatment of pediculosis. D.D.T. is

preferable to lethane because one treatment properly carried out should cure every case. This substance will not, however, be available till after the war. Lethane will cure a large proportion of cases with one application, but two treatments at a week's interval will give certain cure. In order to obtain good results the details of the application of lethane should be carefully observed. Two or three teaspoonfuls of the oil are used for one treatment. The hair is parted, and 2 or 3 drops from the teaspoon or pipette are dripped on to the scalp. This is repeated in from 12 to 20 different areas all over the scalp. With the finger-tips the scalp is vigorously rubbed for two minutes to ensure equal distribution of the oil. Any oil which trickles down the forehead or behind the ears should be wiped off with cotton-wool and vaseline applied.

The following substances proved ineffective in the treatment of pediculosis: 20% solution of dettol, derbac soap, concentrated infusion of quassia, 12.5% formalin soap mixture (M.O.H. Memo., 1940), 0.1% aqueous solution of mercuric chloride, oils of cedarwood, citronella, and lemon-grass, and lauryl thiocyanate.

LOCAL EFFECTS OF INTRAMUSCULAR INJECTION OF SOLVOCHIN*

BY

FRANK HAWKING, D.M.

(From the National Institute for Medical Research, London)

Solvochin is a soluble preparation of quinine, designed for intramuscular injection and supplied by the Camden Chemical Co. Ltd. According to Cooke and Wingfield (1944), 2 c.cm. contains 7½ gr. of quinine base together with phenazone. The reaction is pH 7.2. It has been recommended by Cooke and Wingfield (1944) and others for the treatment of malaria, on the ground that intramuscular injection is painless; some hundreds of injections were given by these observers without any serious complication, although a tender inflammatory induration was once noted.

The present investigation was undertaken to study the action of this preparation upon the tissues at the site of injection and to compare it with those of mepacrine and of quinine dihydrochloride (Hawking, 1943, 1944). The technique was the same as that used in the previous studies. The solution in the ampoule of solvochin was diluted with sterile isotonic saline, 1 c.cm. being made up to 7.5 c.cm., so that 0.5 c.cm. contained 16.3 mg. of quinine base. This corresponded to 20 mg. quinine dihydrochloride in 0.5 c.cm. injected during previous studies (Hawking, 1944). Injections were made intramuscularly into the thighs and loins of rabbits and also subcutaneously on the abdominal wall. Altogether 14 intramuscular injections were made and 4 subcutaneous ones. Two control injections with 0.5 c.cm. normal saline were also made intramuscularly; no sign of local injury due to these control injections was found. The animals were killed after 1 to 8 days. The site of injection was inspected macroscopically, and pieces of tissue were fixed in formol-saline and studied by the usual histological methods, staining with haematoxylin and eosin and with haematoxylin and van Gieson.

Results

Macroscopic Appearances.—In the muscles of the *loin* there was a dark-red fusiform mass (necrosis) with a narrow yellow border (leucocytic reaction); typical dimensions were 3 cm. by 0.9 cm. by 0.6 cm. In the *thigh* the picture was more varied. In some cases there was a dark-red mass 2 by 1 by 0.8 cm. lying longitudinally in the surface of the muscles along the sciatic nerve; in other cases there were small punctate haemorrhages, or the surface of the muscles appeared whitish and roughened. The muscles of the rabbit's thigh are divided by many planes of loose connective tissue, and solutions injected into the thigh are usually distributed along these planes, *between* the muscles rather than inside them. In the loin the muscles form a compact mass, and solutions injected are confined to the interior of the muscle. At the site of *subcutaneous* injection there was no macroscopic evidence of tissue-reaction.

Histological Appearances.—In the *loin* there was an area of coagulative necrosis with variable amounts of haemorrhage as described above. At the margin of this area there was a fairly thin zone (1 to 2 mm.) of leucocytic reaction. On the first day after injection many of the leucocytes were polymorphs, and fibrinous fluid was sometimes present; after 5 to 8 days most of the leucocytes were large mononuclears, and granulation tissue with fibroblasts was present. After 8 days some of the necrotic muscle fibres were becoming calcified. In the *thigh* the amount of necrosis was variable. In some slides there were long areas of necrosis and haemorrhage as described above. In others the necrosis was limited to the superficial layers (2 to 6 fibres deep) on the surface of the muscles. Adjacent muscle fibres were shrunken and basophilic. The neighbouring connective tissue was moderately distended with fluid and lightly infiltrated by leucocytes. After 8 days granulation tissue was present. In the *skin* there was necrosis of the subcutaneous layer of muscle for a short distance, and in one case there was necrosis of the epithelium over a small area. The adjacent connective tissue showed a little fluid and a few leucocytes (small round cells).

Discussion

The lesions produced by the injection of solvochin containing 16.3 mg. of quinine base were indistinguishable in extent from those caused by the injection of a corresponding amount of quinine dihydrochloride, as seen in the previous study (Hawking, 1944).

Summary

Solvochin was injected intramuscularly and subcutaneously into rabbits. Necrosis of the muscle was caused at the site of injection. The lesions were indistinguishable in character and extent from those caused by the injection of a corresponding amount of quinine dihydrochloride.

Acknowledgments are due to the Camden Chemical Co. Ltd. for kindly supplying the solvochin used, and to Mr. F. J. Higginson for the histological preparations.

Medical Memoranda

Foreign Body in Lung for Thirty-one Years

This case is published not only for its own interest but to reinforce a plea for the more frequent use of the bronchoscope in diagnosing intrathoracic lesions. The passage of a bronchoscope involves comparatively little disturbance to the patient and can almost invariably be done under local analgesia. The presence of even gross sepsis is therefore no contraindication.

CASE REPORT

A man aged 67 was admitted to the West Norfolk and King's Lynn General Hospital under Dr. Holmes Watkins on Oct. 27, 1943. There was a history of old tuberculosis of the lung, but he had been quite well for many years. On Sept. 22 he began vomiting dark fluid, and a barium meal showed a large atonic stomach, but no evidence of ulcer or neoplasm. Screening of the chest revealed what appeared to be a cavity at the right base, and a skiagram showed a large patch of pneumonitis there. A profuse purulent sputum grew *Str. viridans*, pneumococci, and *Micrococcus catarrhalis*. No tubercle bacilli were seen.

On Nov. 3, at Dr. Watkins's request, I undertook a bronchoscopy. Premedication was by omnopon and scopolamine, and in addition he was given an amethocaine hydrochloride pastille to suck 20 minutes beforehand. Under cocaine analgesia the bronchoscope passed quite easily, and when it entered the right bronchus a well of pus was seen. This was aspirated and a dark foreign body was seen lying across the bronchus about 4 cm. down from the bifurcation of the trachea. It was removed without great difficulty and found to be about three-quarters of an inch of the vulcanite mouthpiece of a pipe.

Questioned subsequently, the patient recollected an accident in 1912, when he fell from his bicycle and his pipe was broken in his mouth. His palate was lacerated at the time but healed well, and he had never thought any more about it. Unfortunately, infection in the lung spread rapidly, and he died on Nov. 15.

The astonishing thing is that a foreign body of this size could have remained blocking the bronchus for 31 years without giving rise to serious trouble. It is possible that this may be due to the fact that the airway through the centre of the vulcanite had remained patent and that he was therefore able to get enough air backwards and forwards through it to ventilate his lung. Careful examination of the vulcanite showed no corrosion or disintegration at all.

J. LEWIN, M.B., F.R.C.S.,
Senior Surgeon,
West Norfolk and King's Lynn Hospital.

Recurrent Dislocation of Ankle due to Rupture of External Lateral Ligament

It is still a fact that many cases of recurrent dislocation of the ankle due to a rupture of the external lateral ligament pass undiagnosed and untreated. Such a case usually presents itself with a history of a recent sprain. On examination the ankle is swollen, bruised, and painful. However, on questioning, the patient admits having had previous sprains of varying severity. On the other hand, the case may present itself with a history of recurring slight sprains and a general feeling of weakness in the ankle-joint.

The outstanding fact in the history of a case of ruptured external lateral ligament is an original injury of some severity. Further examination of the ankle does not elicit any more inversion than is found in a normally sprained ankle without a ruptured external ligament. Straight radiographs, both lateral and antero-posterior, show no evidence of the ruptured ligament. For this to be demonstrated the muscle spasm has to be relieved by an injection of novocain on the outer aspect of the joint. The result is as shown in the accompanying radiograph (Fig. 1).

A Suggested Operation

The only treatment for an ankle with a rupture of the external lateral ligament is operation. The following technique was devised by me.

At operation the old rupture is quite apparent. The ligament is repaired by splitting the tendon of the peroneus longus from above downwards. The detached end is then threaded through the external malleolus and through the os calcis (Fig. 2). The value of this method is that it is easy to perform and that it reconstitutes the ligament. At the same time no muscle is damaged, as the remaining half of the tendon hypertrophies.

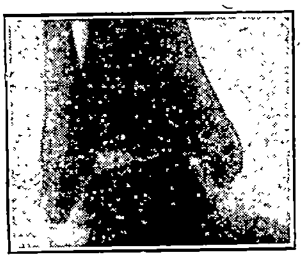

FIG. 1

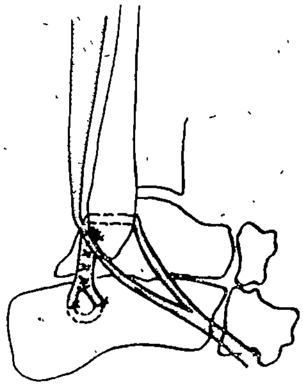

FIG. 2

FIG. 1.—Radiograph showing dislocation of the astragalus.
FIG. 2.—Diagram showing half of the peroneus longus tendon threaded through the external malleolus and the os calcis, and back again on itself.

The radiograph shown is that of a patient upon whom I operated. When first seen she was aged 32. On examination she had what appeared to be a severe sprain or a fractured ankle. Her history, however, revealed that this occurred every few months. She also clearly remembered a severe sprain as a child. This undoubtedly was the time that the ligament was ruptured. Operation revealed the old tear of the ligament. The patient has had no further trouble since the operation.

I should like to thank Mr. A. T. Fripp, F.R.C.S., as it was while assisting him at one of his cases that I devised this operation.

E. HAMBLY, M.B., B.S., F.R.C.S.,
Surgeon, E.M.S. Royal National
Orthopaedic Hospital.

Reviews

SOCIAL WORK FOR THE TUBERCULOUS

Social Work for the Tuberculous—A Practical Guide. By Harley Williams, M.D., and Irene Harbert. (Pp. 153. 5s.) London: National Association for the Prevention of Tuberculosis.

The presentation of information on social work, in any of its many forms, in a concise and readable manner, is a difficult task, and that side of it devoted to tuberculosis is no exception to the rule. The authors of this book are therefore to be congratulated on having produced a valuable guide containing a storehouse of useful knowledge in so small a compass as 153 pages. The title of the book is a little ambiguous, but the subject-matter is for the most part a clear and well-constructed summary of the management of the tuberculous patient in his home and gives an excellent account of the assistance which is available under Memorandum 266T and the help provided by care committees. It is agreed that "if its principles and ideals are grasped the care worker will be more confident in her own judgment."

In detail, however, there are some points which need correcting and revision. Where the book touches on clinical matter there is a certain degree of confusion, and in some places it gives rather misleading information. For instance, a positive skin test does not always mean there has been contact with an open case of pulmonary tuberculosis: it may result from drinking infected milk. It would have been useful to have more information on the subject of pensions and the help given by the British Legion in this direction. There is a tendency to draw a too optimistic picture of the assistance which the tuberculous patient will receive under the Ministry of Labour and National Service rehabilitation scheme, and there is little guide as to the employment of the "open case" except in the village settlements. Certain paragraphs will no doubt be redrafted in future editions, for this book will be helpful to social workers for many years to come.

A useful index to agencies for personal aid is given at the end of the book as well as a general index. The well-defined and clear fount of type makes the text easy and pleasant to read without fatigue.

INDUSTRIAL OPHTHALMOLOGY

Industrial Ophthalmology. By Hedwig S. Kuhn, M.D. (Pp. 294; illustrated. 32s. 6d.) London: Henry Kimpton. 1944.

Industrial ophthalmology is not synonymous with a study of industrial eye injuries any more than ophthalmology in general is merely the study of the causes of blindness. Different occupations require different degrees of visual acuity, stereopsis, muscle balance, adequate illumination, and capacity for quick visual judgments. Furthermore, different industries involve varying degrees of ocular fatigue, and danger of damage from mechanical or toxic factors. The conditions under which some industrial processes have to be carried out may be so trying that special measures are needed to enable the worker to see clearly and comfortably for prolonged periods. Studies on these and kindred aspects have appeared in the periodical press and in monographs, but there is no systematic survey of industrial ophthalmology as a whole. It is perhaps also no exaggeration to say that there is as yet no comprehensive formulation of the problems.

The appearance of Dr. Hedwig Kuhn's *Industrial Ophthalmology* is therefore a welcome portent, for here at last is an attempt to survey the field as a whole. The numerous photographs of factories, workrooms, and machines, and of workers concentrated on particular tasks are in themselves a substantial contribution to the formulation of the problems of industrial ophthalmology. Incidentally they also show how much has been done in isolated factories, here and there, to meet some of the problems. The chapter devoted to eye protection shows forcibly enough that this is not merely a matter of goggles; like all general remedies goggles tend to conceal more dangers than they have overcome. The introductory chapter, with its stress on the need for tests to eliminate those who are visually unfit for particular tasks, is particularly illuminating; to most ophthalmologists the whole concept and its application will prove distinctly new. The chapter on visual skills is an excellent essay on the adaptation of workers to their jobs. Even at this stage in the development of industrial ophthalmology it is clear that, as distinct from an encyclopaedic knowledge of the details of various industrial processes, there are certain general principles that are applicable throughout industry and readily adapted. To have shown this is a substantial achievement for a pioneer effort in the writing of a textbook on a new subject. Dr. Kuhn's book in addition contains a mass of detailed information, and there are particularly useful sections on toxic hazards and on danger from radiant energy. It is regrettable that the high achievement of this book is marred by the inclusion of a considerable amount of irrelevant and ill-balanced information, and by a style that lapses alternately into purple passages and sheer slang.

THE SICK AFRICAN NATIVE

The Sick African. A Clinical Study. By M. Gelfand, M.B., Ch.B., M.R.C.P., D.M.R. (Pp. 372; illustrated. 25s.) Capetown: The Post-Graduate Press in association with the Stewart Printing Co., Ltd. 1944.

Most textbooks on tropical medicine in describing diseases in the Tropics consider these mainly from the point of view of the European who is merely a visitor in a foreign land. Only those diseases which are not found in his own country—the so-called tropical diseases—are dealt with, while those which are common to both tropical and temperate countries receive little consideration. In *The Sick African* the author deals almost entirely with the native, and considers the European only in so far as his susceptibility and response to certain diseases differ from those of the African.

The native is a very different person from the European. He has little or no education, is under the influence of the witch doctor, and is always afraid of offending the spirits of his ancestors. He is fatalistic, and is often reluctant to consult a white man about his symptoms. When he does so it is with difficulty that he is persuaded to carry out a long course of treatment, for immediately his symptoms abate, though cure has not been effected, he will leave hospital and not return for further advice or observation. On this account treatment must be as rapid as possible, even though it is understood that this is not entirely satisfactory. The solution of many of these difficulties, in the author's opinion, is the African-trained native doctor, who understands the native mentality and speaks his language as no European can ever hope to do. All these and many other aspects of medical practice among Africans are discussed in the two introductory chapters of the book. There follow others on malaria, bilharziasis, hookworm disease, leprosy, yaws, and the many other conditions to which the native is liable. It is noted that he far more commonly suffers from those diseases which occur in temperate climates than he does from those that are purely tropical. Dr. Gelfand has had a wide experience of native practice, and the advice he gives as to the methods of handling and treating the native will be invaluable to all who find themselves in the position of having to carry on this kind of work.

As Col. A. P. Martin says in his foreword, this is a book which in an outstanding manner meets the needs of all workers in the African field of tropical medicine.

LIP-READING AND DEAF AIDS

Lip-reading and Hearing Aids. By Irene R. Ewing, M.Sc. Second edition. (Pp. 73. 4s. 6d.) Manchester: The University Press. 1944.

It has long been known that deaf children acquire the art of lip-reading with comparative facility and require relatively little teaching, while for adults the process is more difficult, and it has been said sometimes to be impossible. The services of Mrs. Irene Ewing to the deaf are well known, and one of them is the compilation of this little book, which describes the nature and scope of lip-reading and the correct approach to the problems of both teaching it and learning it. The difficulties are seen from the sides of both teacher and pupil. The importance of combining lip-reading with the use of a proper hearing aid, so that the use of one sense organ reinforces the activity of the other, is established, and Mrs. Ewing shows that by following her methods the assumption that adults cannot learn lip-reading is ill founded. Those who are becoming deaf or have suddenly become deaf and are determined to make a serious effort to overcome the disability will find not only that this little book is of great assistance but also that it brings a message of needed encouragement and hope. The methods described are not intended for children.

Notes on Books

Messrs. E. and S. Livingstone of Teviot Place, Edinburgh, have published a third edition of Miss Lois Oakes's *Illustrations of Bandaging and First Aid*, which received praise in these columns on its first and second appearances. It is a very useful introduction to the art of bandaging and is likely to fill for long to come a niche in first-aid literature. The material has been revised for the new edition and several new features added—for example, a section on how to "blanket" a stretcher, how to lift and lower a patient, and how to remove an unconscious person from a smoke-filled room. An addition is four pages of coloured pictures entitled "Typical War Wounds," taken from Mr. Hamilton Bailey's book *Surgery of Modern Warfare*. The volume is very freely and clearly illustrated throughout. Its price remains at 6s., postage in this country 6d. extra.

Preparations and Appliances

A CHEAP AND EFFECTIVE SUBSTITUTE FOR UNNA'S PASTE

Lieut. J. J. Wild, R.A.M.C., writes:

In 1943, faced with the shortage of elastic bandages and a large number of chronic ulcers of the leg, mainly varicose requiring out-patient treatment, I decided that a substitute for Unna's paste must be found. With the kind co-operation of Mr. Soulsby, the pharmacist at North Middlesex County Hospital, a preparation was evolved which not only fulfilled this purpose, but has proved superior to Unna's paste in two ways at least, namely: (1) No heating is required before application. (2) Low cost and easy availability.

The Preparation.—The basis of the preparation is methyl cellulose, a water-soluble tragacanth substitute. This goes under various trade names. The product used by me was "W.F.Z.," supplied by Imperial Chemical Industries, Ltd. (South-Eastern Division, Dyestuffs Section), Belmont, The Ridgeway, Mill Hill, N.W.1. This is a commercial grade of methyl cellulose, and contains traces of heavy metals so that it is unsuitable for internal administration or topical application to open wounds. Nevertheless, bearing these points in mind constantly, I have found that it is harmless to the intact skin.

Details of Preparation.—"Cellofas W.F.Z.," described as a technical grade of methyl cellulose, is a cream-coloured fibrous cellulosic material. In low concentration in water it has the property of forming a viscous solution, which dries slowly in air, giving a celluloid-like film which redissolves in water. The current cost is 2s. 10½d. a lb. The substitute is easily prepared by taking 95 parts of water and 5 parts of W.F.Z. Leave overnight, stir thoroughly, and then adjust the proportion to 3% with water. Add 20% of zinc oxide and stir well. No doubt lighter concentrations, such as 5% W.F.Z. and 30% zinc oxide, could be used, but this would not pour and would give a stiffer paste. W.F.Z. is not an antiseptic, and will support growth of fungi. For this reason it has always been freshly prepared for my use. No attempt has been made to sterilize the preparation as it does not come into contact with the open lesions. But should this be thought necessary, autoclaving should not affect it.

Method of Use.—The preparation is applied cold on to a wet bandage with a brush, and layers of wet bandage are impregnated with it as for Unna's paste. The final bandage is a dry one and serves to protect the patient's clothing. Drying occurs in a few hours, and the patient is instructed to moisten the dressing if it gets too hard. This procedure is rarely necessary. About four layers of bandage are usually enough.

Clinical Applications.—(1) Varicose ulcers: All ulcerated areas and vulnerable skin are covered with lint after applying the required dressing; then the supportive dressing is applied. (2) Thrombophlebitis: Used as a supportive bandage. (3) For lower limbs after plaster-cast immobilization: I used the preparation for this purpose, in preference to adhesive elastic supportive bandages, for eight months at the Miller General Hospital, Greenwich; no skin reactions were observed. (4) As an occlusive dressing in suspected dermatitis artefacta.

The preparation has been in constant use at the North Middlesex County Hospital for two years, without trouble. The paste is entirely satisfactory, and, bearing in mind the high cost of Unna's paste and the need for economy in glycerin and gelatin at this time, it is gratifying how efficient a substitute this preparation has proved. It might even be deemed to have superseded Unna's paste.

My thanks are due to Mr. Soulsby, the pharmacist, to Sister Peers, and her nursing staff at the hospital for their willing co-operation in evolving this preparation.

TREATMENT OF INFECTIVE HEPATITIS

Function and structure in the liver of experimental animals can be profoundly modified by diet. If an excess of fat is given the liver first becomes fatty and later undergoes a diffuse fibrosis of the portal type.[1] Presumably the accumulation of fat interferes with the activities of the cells. The evil effect of fat can be prevented by the so-called lipotropic factors, which promote the transfer of fat from the liver to the depots. Choline and methionine are the most important of these. Choline is a component of lecithin, while methionine is one of the essential amino-acids; it contains sulphur and also has some chemical affinity with choline. If the proportion of protein in the diet is greatly reduced more critical and dramatic changes may occur in the liver, similar to those of acute and subacute necrosis in man.[2] After a latent period the necrosis occurs abruptly and is often fatal. It can be prevented by methionine but not by choline. Finally it has been shown that in dogs which have been depleted of protein the resistance to hepatic poisons is impaired. Miller and Whipple[3] have shown that if these protein-depleted dogs are given methionine shortly before chloroform anaesthesia they will be protected from poisoning. A combination of choline and the sulphur-containing amino-acid, cysteine, has a similar effect, but not choline alone. Protection can be given up to 4 hours after the anaesthetic, but not later. Very similar results have been obtained in neo-arsphenamine poisoning. Two points must be made about the relation between protein metabolism and liver poisons. The first is that the favourable effect of protein supplements or thio-amino-acids has been observed only in animals which had been depleted of protein; there is no evidence that they are of value in animals which have been receiving an abundance of protein. The second point is that the effect is purely prophylactic, and that a superabundance of proteins and amino-acids has not been shown to be of value in the treatment of experimental animals with hepatitis. In fact the reverse is the case. Bollman and his collaborators[4] have shown that if the dog's liver is damaged by ligating the common bile-duct or by administering a daily dose of carbon tetrachloride, a high-protein regimen is actively harmful and accelerates the development of ascites and hepatic insufficiency. In another series of experiments,[5] in which rats were subjected to repeated exposure to carbon tetrachloride, the average duration of survival on a normal mixed diet was represented by the figure 100; the duration of survival on high-carbohydrate, high-protein, and high-fat diets was found to be equivalent to 205, 104, and 59 respectively.

It is appropriate to consider the bearing of this experimental work on the treatment of infective hepatitis and allied conditions in man. There is enough evidence to suggest that in the recent epidemics of jaundice in the Mediterranean theatre of operations and elsewhere the relative incidence has been much lower in native troops, but the relative mortality has been higher; the difference in mortality may well be due to the prophylactic value of the higher protein content of the diet of white troops. In treatment there has been a tendency to increase the protein as well as the carbohydrate in the diet at the expense of the fat, but it cannot be said that any convincing evidence has been obtained to justify such a break with tradition. Beattie[6] has claimed that the average time spent in hospital in a large series of patients with acute hepatic dysfunction is inversely proportional to the protein intake. As the appetite is inversely proportional to the severity of the illness, this may be only another way of saying that the duration of stay in hospital is directly proportional to the severity of the illness. Beattie also speaks favourably of the value of casein digests, cystine, methionine, and choline, but he indicates that, owing to the great variability of infective hepatitis, it would be impossible to prove a statistical effect from these supplements without very large numbers of cases. Turner and co-workers,[7] whose experience is based on over 4,000 cases of homologous serum jaundice, state bluntly that methionine and choline failed to yield beneficial results. Richardson,[8] in a small series of cases of infective hepatitis not yet published, has failed to demonstrate any effect with choline. Peters and co-workers[9] have observed no more than a slight benefit from cysteine and methionine in the treatment of post-arsenical jaundice. It is important to realize the conditions of this trial. Mild cases of jaundice and patients jaundiced for more than 14 days were excluded from the analysis, so that only 150 out of a total of 468 patients were left in the trial. The duration of illness in the methionine-treated cases averaged 20 days, as compared with 26 days for the controls, and there was considerable individual variation. So small an effect in so carefully chosen a group may be statistically significant and yet remain clinically insignificant. In the present number of the *Journal* we are publishing details of therapeutic trials of methionine in infective hepatitis by groups of workers at Cambridge and Oxford. In these two series there were 68 treated cases and 68 controls. The conclusion is reached that treatment with methionine has no significant effect on the severity or duration of infective hepatitis or the incidence of relapses. It may be pertinent at this point to reflect on the cost of treatment with methionine. In a recent price list of fine chemicals methionine was quoted at 7s. per gramme. The daily dose is 5 grammes, and the average duration of treatment 14 days. This would work out at nearly £25 per patient, and the cost would be unlikely to be reduced more than 50% by large-scale production, as the synthesis of methionine is difficult. Moreover, more methionine might mean less mepacrine and less D.D.T. Finally, it would appear that methionine may have an important place in the treatment of burns[10] and exfoliative dermatitis.[11] In the present phase of scarcity, therefore, there can be little excuse for recommending methionine in the treatment of jaundice.

What, then, are the indications for treatment in infective hepatitis? The first is rest in bed, which should be continued until the liver is no longer tender and the urine is free from bile, preferably by the delicate Hunter reaction. The routine diet should be high in carbohydrate, low in fat, and high in proteins. The emphasis should be on the carbohydrate, and fat should not be reduced to a level at which the food becomes dry and unpalatable. Palatability of the diet and avoidance of undernutrition are indeed primary factors in the treatment of a disease in which loss of appetite is the leading symptom, and Turner came to the sobering conclusion that patients who were allowed to choose their own diet did at least as well as, and in some instances perhaps better than, the average. Fresh milk is often well taken; the cream which separates on standing can be removed, though this is not absolutely necessary. Dried milk is often rejected. Fruit drinks ensure a large intake of fluid, carbohydrate, and vitamin C. Regularity and frequency of food intake are probably of greater importance than exactness in the composition of the diet, and Turner believes that if patients were given an infusion of glucose for each meal avoided or vomited some disasters might be obviated. Routine treatment with dextrose and insulin,[12] however, is of no advantage, and the same appears to be true of extra vitamins, calcium salts, and liver extract. There is a suggestion that both liver extract and plasma may produce unpleasant reactions. In conclusion, it would seem that infective hepatitis provides one more example of the care that must be taken in applying knowledge gained in the field of nutrition to the treatment of infective disease.

THE ABUSE OF REST

One of the things which most impressed the medical visitor to the United States twenty years ago was the sight of young women sitting about the lounges of the hotels in Rochester, Minnesota, five days after their thyroid glands had been resected for toxic goitre. The idea that a thyrotoxic patient should be kept in bed for weeks or months had been so deeply ingrained that it was a shock to find the rule broken with apparent impunity. Pressure on beds at the Mayo Clinic was heavy in those days, and now that pressure on beds is everywhere heavy the value of rest is being questioned in every field of therapeutics. A recent symposium in the *Journal of the American Medical Association* speaks roundly of the abuse of rest and the evil sequels of recumbency. Rest is blamed for bone atrophy, muscular wasting, vasomotor instability, constipation, cathartic habituation, backache, and many other chronic disabilities. In later life it favours the onset of bladder trouble, pulmonary oedema, and uraemia. Harrison[1] points out that John Hunter and Sir James Mackenzie suffered from angina pectoris, and their hearts bore the scars of cardiac infarcts at necropsy; yet both men worked hard for some twenty years after the beginning of cardiac symptoms and probably ten years after serious cardiac infarction. Yet neither ever remained in bed for any long period of time. Harrison argues that there is no proof that rest in bed, carried out for many weeks after symptoms have disappeared, is of value in the physical management of the patient with congestive failure, angina pectoris, or myocardial infarction. He brings evidence from animal experiments to suggest that nowadays we confine the patient to bed needlessly long after a coronary thrombosis, and hints that this may even favour a second thrombosis or a pulmonary embolus. Harrison's views did not go without challenge. It all depends on what you mean by rest, as Dr. C. E. M. Joad would say. There is general condemnation of strict recumbency, particularly when it is enforced by sedation and punctuated by periods of violent exertion on the bed-pan; but not even "global war" can alter the fact that the rate of metabolism and the work of the heart are diminished by rest. Levine[2] is undoubtedly right when he points out that strict bed rest in heart failure may bring about pulmonary congestion from redistribution of blood and oedema fluid, and pulmonary embolism from the thrombi which form in the stagnant blood in the legs when the calf veins are compressed in the horizontal position. These risks can be diminished by a modicum of activity and the use of a chair until oedema and congestion have been relieved by appropriate medication. But in advising that rest need not be prescribed for a longer period than two or three weeks after the more acute and alarming symptoms of a coronary thrombosis have subsided Harrison perhaps overstates the case. Both in coronary thrombosis and in acute rheumatism the majority of physicians would feel it wise to keep their patients at rest until the inflammatory process has subsided, though this need not mean strict recumbency, and the use of the commode need not be forbidden. It is difficult to defend any arbitrary period of confinement to bed, and treatment should be suited to the individual on the basis of the severity of the attack and the course of the fever, the leucocyte count, and the erythrocyte sedimentation rate.

The value of rest in pregnancy and after confinement is a fruitful topic of debate, and in both this country and America there are numerous advocates of a reduction in the lying-in period. This is not a simple problem, for it is linked up with the establishment of lactation and the psychology of motherhood. It will be generally agreed, however, that rest and regular hours of infant feeding can sometimes be too dearly bought; mother and child are reciprocal parts of the family whose integration in the puerperium is no less important than the involution of the uterus. Convalescence from a surgical operation is a simpler problem, and Powers[3] presents some striking figures for 100 consecutive patients who were allowed to sit in a chair and to walk on the first day after major operations. He indicates that local complications such as the breakdown of wounds or hernia are actually less common in these circumstances, while the remote complications of operation are greatly reduced. The patient is not "deconditioned," as he is by prolonged rest in bed, and the return to work is accelerated. In orthopaedic surgery the aim has long been to localize rest as sharply as possible and avoid general immobilization, and anyone who has seen the work of our new accident services will have been surprised by the short time in which patients are able to get about in comfort after fractured skulls or disabling injuries. Menninger[4] concludes the series of articles with an amusing criticism of the Weir-Mitchell treatment and of similar measures whereby it is hoped to cure psychological illness by rest cures, relaxation treatments, or holiday trips. "The things that disturb people are not what they hear on the radio: they are what is in their hearts." In psychological breakdown due to exposure to prodigious stress, such as occurs in battle casualties, prompt and complete rest is indeed of enormous benefit, and it must be secured by heavy sedation. But when men break down under conditions of peace they do so from the turning inward of aggressive tendencies, and they require not rest but mental reorientation, physical exertion, and the directed use of muscles to prevent the accumulation of this self-destructive energy.

This American symposium is written under the influence of wartime shortages of beds and doctors, and some of it has a flavour of special pleading. Nevertheless it should be of value in making us question customary procedures, particularly in hospital practice. In recent years a number of these traditional procedures have been revised. The ritual purgation of patients[5] is no longer condoned, and the patient with a haematemesis is fed. Morphine is regarded as one of the best drugs for renal dyspnoea, instead of being frowned on, as in the past. A hospital is now known to be a dangerous place for a small infant, and it may be equally bad for the old and feeble, who never again pick up the thread of activity once they have let it drop. Absolute rest gained a well-deserved reputation in tuberculosis, but it may be a veritable bed of Procrustes if it is applied to every form of serious illness. Whenever we put a patient to bed we should ask ourselves what we hope to achieve; and it must be something more than a tidy ward, a convenience for examination, or a substitute for a convalescent room. The folly of treating obesity in bed, or of balancing the diet and insulin in a diabetic under conditions of complete rest, is only too common a sight in hospital wards. In every illness, too, we should ask ourselves how the individual patient reacts to rest in bed. For many it is a sheer delight, but for others it is a tedious ordeal which produces a continual mental strain and is much less restful than a discreet amount of activity.

ENCEPHALITIS IN RUBELLA AND MEASLES

As it is often difficult to distinguish atypical rubella from scarlet fever and measles, particularly in the adult, it is as well to be chary of attributing severe complications to the mildest of these three infectious diseases—rubella. But they nevertheless occur in some outbreaks. Polyarthritis, for example, was a feature of rubella in the early days of the present war. A much rarer complication is damage to the nervous system. Bénard's[1] experience of this must be unique, for he encountered no fewer than 13 cases with meningeal symptoms among 291 soldiers treated for rubella in a Versailles military hospital. Reviewing 36 recorded cases of meningo-encephalitis following rubella, Falger[2] notes that 22 were in adults, and, in all, 8 patients died. His own patient, a woman of 26, began with a mild attack of rubella, fell into a deep coma on the eighth day after the eruption, and died within 24 hours. Many of the recorded cases have been mild, and it appears that the complication is either rapidly fatal or clears up completely.

The encephalitis of measles is a more serious matter. Post-mortem examination of the brain in rubella encephalitis shows that the type of reaction is inflammatory; a degenerative, demyelinating process is seen in post-vaccinal and measles encephalitis. The fatality rate for measles encephalitis is high, but varies from epidemic to epidemic. In a follow-up study of recovered cases Litvak and his colleagues[3] found permanent changes in 22 out of 32 (69%)—a proportion approximating to the 65% already recorded by Ford.[4] The permanent manifestations were as varied as the acute stage, but it is interesting to note that, in patients observed over many years, neurological disorders faded gradually and were replaced by disorders of behaviour. In the large New York epidemic reviewed by Litvak only 1 in 1,300 cases of measles developed encephalitis—an incidence considered to be unusually high. The exact cause is still in doubt. The common view is that the histological changes are caused by toxins from a systemic virus infection, and are not the result of a direct attack by the virus. Even if the encephalitis were due to the virus of measles it still remains unlikely that measles serum would have any effect on virus fixed to nerve tissue. In practice the results of even large intravenous doses of convalescent measles serum have been unconvincing, although Mitman[5] noted a rapid response to the intravenous injection of 20 c.cm. of serum obtained from a patient convalescing from measles encephalitis. Until it has been shown beyond doubt that measles serum is useless the physician in charge of a case will feel inclined to give the patient the benefit of the doubt and inject serum when the signs of encephalitis appear. No sulphonamide compound has any action in measles other than on secondary invaders such as haemolytic streptococci and pneumococci. The initial phase of the disease is not influenced by sulphonamides, nor, it appears, is measles encephalitis.

THE HOSPITAL ALMONER

Not long ago the principal function of the hospital almoner was regarded as assessing how much a hospital patient might be expected to pay for his maintenance. Sir William Beveridge, in an address to the Institute of Hospital Almoners the other day, said that he himself had had that same notion until later he learned that the almoner fulfilled a much wider medico-sociological purpose. Her job was that of "helping people, both through the best use of their own capabilities and through the resources of the family and the community, to overcome personal and social difficulties and to achieve the fullest possible measure of health and independence." New personal problems constantly arose in sickness which could be solved only by personal help of this kind, and therefore, in addition to what was provided from the medical and nursing side, the work of the almoner had its own distinctive scope and importance. He mentioned that when preparing his report he interviewed a group of almoners and asked them whether, if the financial assessment side of their work were taken away, it would make an enormous difference to their duties, and he was assured that what they believed to be their most important duties would remain. Even the earlier notion of the almoner's role had its value, for the financial assessment was designed to ensure that no one went without necessary hospital treatment owing to lack of means. There were, however, better ways of bringing about the same result. One of them was represented by hospital contributory schemes; but still more to be preferred, in his view, was a universal and compulsory system of insurance and a provision such as the Government contemplated in the White Paper. The criticism had often been urged against such schemes that they discouraged personal initiative. But the material benefits proposed in his report were only the minimum provision, and ample room was left for individual effort to obtain more than the minimum. The whole idea of giving people social security, said Sir William Beveridge, was to free them from material anxiety so that what were sometimes called the things of the spirit might be cultivated. There were those who said that in seeking to ensure material security for all he was taking a low aim. His reply was that, on the contrary, the low aim was taken by those who supposed that unless people were afraid of starvation they would sit down and do nothing.

RESEARCH AT THE PHARMACEUTICAL SOCIETY

The annual report of the College of the Pharmaceutical Society for 1944 is of considerable interest. Work which has begun under Prof. H. Berry on an antiseptic for Gram-negative organisms has made a promising start. It is generally known that we now have in penicillin, the sulphonamides, proflavine, and other recently introduced antibacterial substances a means of ridding wounds from Gram-positive cocci, anthrax, and the gas-gangrene organisms. Hitherto, however, there has been no means of removing *Ps. pyocyanea* and *Proteus vulgaris*. Prof. Berry has found that β-phenoxyethyl alcohol, which he calls "phenoxyetol," is active against *Ps. pyocyanea* in a concentration of 0.4%. Since this substance can be mixed with penicillin and does not interfere with the action of penicillin (or of the sulphonamides or proflavine) phenoxyetol can be used in conjunction with penicillin. Clinical trials have been undertaken. Phenoxyetol is a liquid which does not affect the unbroken skin, and its antibacterial action is not diminished by serum. It was first tried by Dr. J. Gough for tuberculous cavities secondarily infected with *Ps. pyocyanea*, in a 2.2% aqueous solution. This has also been used for burns and superficial wounds. Daily applications eliminate *Ps. pyocyanea* in some cases and reduce their numbers in others; when that micro-organism is eliminated clinical improvement occurs even though staphylococci increase. Phenoxyetol incorporated (2%) in penicillin cream keeps the cream sterile during its use in the wards by killing air-borne organisms which produce a penicillinase. Moreover, the cream kills *Ps. pyocyanea* as well as organisms sensitive to penicillin.

The other direction in which striking progress is being made is in the study of the release of the cortical hormone from the suprarenal glands. The beginning of this work, which is carried out by Dr. Marthe Vogt, was described in last year's report. It has now been shown that the intravenous infusion of adrenaline stimulates the suprarenal cortex, and that this effect is obtained with doses of adrenaline which may be liberated in the body when the splanchnic nerves are stimulated. Within a few minutes of the beginning of an adrenaline infusion the output of cortical hormone rises to several times its resting value, and remains there for some time after the adrenaline infusion stops. Dr. Vogt has shown that this effect of adrenaline is a direct action on the cortical tissue and is likely to be related to the large rise in the oxygen consumption of the suprarenal gland which occurs when adrenaline is injected. We have here the clue to the relation between the suprarenal medulla and cortex, which has been a puzzle for 70 years. Although the cortical hormones are the centre of interest in many laboratories in America because of their great importance in the body, hitherto progress has been confined to the chemistry of these hormones, their action when injected, and their excretion. This advance in knowledge of their liberation in the blood is in a new direction by methods of great technical difficulty on which Dr. Vogt is to be warmly congratulated.

UNITED FRONT FOR MENTAL HEALTH

A provisional National Council for Mental Health was formed in the early part of 1943 to take over the work of the Mental Health Emergency Committee and to continue the activities of the Central Association for Mental Welfare, the Child Guidance Council, and the National Council for Mental Hygiene. It is hoped that before this year is much older the amalgamation will be completed. Meanwhile this partly amalgamated body, as its first report indicates, has carried on a many-sided work. It has set up facilities for mental health training for medical officers and other professional workers such as teachers and health visitors. It has paid close attention to the subject of education of the parent. Under its auspices the services of educational psychologists have been lent to local education authorities and others. Information has been disseminated on the setting up of child guidance clinics, of which, at the date of this report, there were 47 in England and Wales with full staffs, and 18 others under medical direction but without a fully qualified psychologist or psychiatric social worker. The social case work department, which is concerned with children under guardianship, mental defectives, maladjusted children, and others, dealt with over 3,000 cases during the year. The council is also responsible for 13 homes of different types, such as emergency homes for mental defectives and agricultural hostels. These last, which are for men on licence from certified institutions, have proved one of the most successful experiments in the community care of mental defectives. There have been some failures in adjustment, of course, but far more successes. It is added that during this early period of amalgamation into the National Council each of the several bodies has learned to understand and appreciate what the others are doing, and the varied experience which each has brought has increased the vitality, widened the horizon, and heightened the value of the work as a whole.

We announce with much regret that Sir Thomas Lewis, M.D., F.R.S., died on March 17 at Rickmansworth. Last December the Presidents of the Royal Society and of the Royal College of Physicians awarded him the Conway Evans Prize in recognition of his great contribution to medical knowledge on the normal and abnormal mechanisms of the heart and the circulation of the blood.

COAL AND ATMOSPHERIC POLLUTION

Dr. A. Parker, Director of Fuel Research under the Department of Scientific and Industrial Research, in a Chadwick Lecture at the London School of Hygiene on coal in relation to atmospheric pollution, said that estimates made before the war put damage to health, buildings, materials, and agriculture in Great Britain by smoke, sulphur, ash, or grit, arising from the use of coal, at not less than fifty million pounds a year. Though it was not possible to prevent pollution entirely, methods were available under which considerable reduction could be achieved. He emphasized, however, that progress would have to be gradual if the demands for various fuels were not to overstep the supply, and there must be a suitable balance if our resources of the different types of coal were to be used to the best advantage.

Efficient Use of Fuel

The wider use of efficient methods for cleaning coal at the colliery before it reached the consumer would reduce the amount of ash, dirt, and sulphur in the coal or coke and the amount of grit carried to the atmosphere. A reduction of pollution would result from more efficient use of fuel because less fuel would be burnt. Efficiency figures showed that there was much room for improvement which could only be achieved in reasonable time by well-planned scientific investigation and technical development, combined with intelligent and skilled operation.

On the domestic side, under ordinary household conditions, the overall efficiency of the open coal-fire was not more than about 20%. The corresponding figure for the general purpose appliances in which coal was used for space heating, provision of hot water, and cooking was somewhat greater because of the heat taken up by the water, but it was probably not more than 25%. Much effort was now being expended in designing open fires to provide not only radiant heat but also convected heat from air heated by passage through ducts adjacent to the fire, the warm air being discharged into other rooms. With systems of this kind the average householder might get an efficiency of 30% in place of 20% with the ordinary open fire. The idea was not new, but the problem was to design a fire not too costly to make and instal and very simple to operate. Dr. Parker estimated that as an overall figure it was unlikely that efficiency in the use of the 60 million tons of coal we burnt for industrial purposes exceeded 50%.

Smoke and Grit in Furnace Gases

With large modern boiler installations equipped with mechanical stokers, little or no smoke need be produced; but such installations with forced draught carried appreciable quantities of ash or grit into the chimney gases. In some instances the grit had caused considerable nuisance in the locality of the boiler house. Most of this grit could be removed from the chimney gases by efficient grit-catchers such as had been installed at the largest electricity generating stations. At certain of the larger electricity power stations in thickly populated areas coals containing not more than 1% of sulphur were chosen for firing the boiler furnaces. In addition, these power stations were equipped for the operation of processes which removed most of the oxides of sulphur from the chimney gases before discharge to the atmosphere. But these processes of treatment to remove sulphurous gases, however, were not easily operated and were expensive. Some efficient but cheaper method was needed to reduce the quantity of oxides of sulphur discharged, suitable not only for the largest but also for smaller boiler installations. It had not been possible in the past, with the large numbers of hand-fired boilers at numerous industrial works, to avoid the emission of smoke, particularly for a time after stoking. Extensive work by the Fuel Research Station during the last few years had developed equipment to modify the doors of marine and Lancashire boilers whereby the emission of smoke could be practically eliminated. This gave, at the right time and in the right way, the extra air required to burn the smoky volatile matter evolved from the fresh coal for the necessary period after stoking.

Pollution from Domestic Fires

The domestic open fire gave out more smoke per ton of coal burned than any other appliance in general use; and about half of the smoke pollution arose from domestic appliances, though they consumed less than a quarter of the total coal used. There were designs of open fire which would reduce the amount of smoke to about a half of that with the open fire of usual type, but they had not yet been tried out in general use by the average householder. Emission of smoke during the early stages of burning up after lighting seemed to be unavoidable. With open fire-grates of suitable design there was no difficulty in satisfactorily burning coke, provided that the coke was in pieces of suitable size.

Substitution of gas for solid fuel would avoid pollution by smoke and grit and would reduce pollution by sulphurous gases to a negligible amount. The use of electricity in place of solid fuel avoided the emission of smoke, but would not prevent pollution by grit and sulphurous gases unless the generating stations were equipped to remove the grit and sulphur from the chimney gases. In general, however, gas and electricity were too expensive for continuous heating in the average house, but they had advantages for short-period intermittent heating and for cooking. In respect of domestic appliances it would seem that encouragement should be given to the use of coke, gas, and electricity in place of coal, so far as was economically practicable, if atmospheric pollution was to be greatly reduced.

COMMITTEE ON REMUNERATION OF GENERAL PRACTITIONERS

The committee recently set up under the chairmanship of Sir Will Spens by the Minister of Health and the Secretary of State for Scotland to advise on the range of total professional income of a registered medical practitioner in any publicly organized service of general medical practice is inviting evidence from the organizations directly interested. The committee will, however, be prepared to receive evidence from interested bodies or persons other than those specially invited. It is requested that those wishing to place their views before the committee should submit memoranda to the Joint Secretaries of the Committee, Ministry of Health, Whitehall, London, S.W.1, before the end of April.

Some reference to the B.M.A.'s procedure for collecting the evidence it proposes to place before the committee will be found in the *Supplement* this week at page 43.

AWARDS TO CIVIL DEFENCE M.O.s

The *London Gazette* has announced the appointment as M.B.E. (Civil Division) of Dr. BALDEV SAHAI KAUSHAL, medical officer, mobile unit, Civil Defence Casualty Service, Dr. JAMES LEITCH KEIR LAWSON, medical officer, light mobile unit, C.D. Casualty Service, Dr. HERBERT STANLEY KNIGHT and Dr. CHARLES HARVEY BATEMAN, medical officers, C.D. First-aid Service, and Dr. WILLIAM THOMAS GARTHORPE BOUL, officer-in-charge, C.D. Casualty Service. DAVID JAMES, staff officer, ALFRED DANDY, BENJAMIN ANDREW GARWOOD, and FREDERICK MARSHALL, party leaders, C.D. Rescue Service, have been awarded the B.E.M. The citations read as follows:

Dr. Kaushal has served with the Civil Defence since the beginning of the war and on more than one occasion has entered confined spaces in dangerous debris in order to give aid to a casualty. When a bomb dropped in the gardens in front of his house he sustained injuries which caused him to lose consciousness. After some minutes he recovered and it was possible to get him into an ambulance. On hearing, however, that there was a person under the debris he refused to go to hospital and attended to the casualty, giving an injection of morphine. He would not leave the site until he was assured that all casualties were cleared. Dr. Kaushal has shown courage and devotion to duty and has been the means of saving many lives.

Dr. Knight has been out on duty at a very considerable number of incidents caused by enemy action, encouraging everyone by his coolness and cheeriness, and inspiring them by his efficiency and perseverance. Dr. Knight has always been ready to tackle any job, no matter how difficult. He has climbed up into partly demolished premises, down into debris-filled basements, and has crawled through tunnels to render first aid and to succour the injured. At one incident, which took nearly 27 hours to clear up, Dr. Knight stood by the whole night and showed great fortitude in remaining until all the casualties were brought out. Dr. Knight has shown courage, devotion to duty, and tenacity of purpose.

Dr. Lawson's courage and constant and expeditious attendance at air-raid incidents during a period of over four years has set a very high example of devotion to duty. On one occasion he was told that a woman with serious injuries had been released from under debris and was lying on the first floor of a wrecked building. The two upper floors of the premises had been shattered by blast, leaving the roof and attic floor overhanging in an unsupported position. Dr. Lawson immediately obtained a ladder and, without thought for his own safety, crawled through a small aperture in the wreckage and gave morphine injections to the casualty.

Houses were demolished by enemy action and people were buried in the debris. Dr. Bateman and Mr. James worked almost continuously in very dangerous circumstances under the wreckage, James directing the rescue operations which enabled the doctor to attend to the trapped casualties. Although the wall above was in danger of collapsing on them, they tunnelled 12 feet into the wreckage to reach a trapped woman crushed by the debris. The doctor remained to give her injections and looked after her until she was released. Dr. Bateman and James showed courage and determination and saved the life of the casualty.

Four people were trapped under the debris of houses which had been demolished by enemy action. Garwood directed rescue operations in a very skilful manner. After tunnelling into the debris and locating the casualties, he set to work to free them. Working for 45 minutes in a confined space, close to a smouldering fire, he managed to rescue two of the victims. To prevent his collapse, he then had to be relieved, much against his wishes. Dandy then went into the tunnel and, by jacking up the debris, was able to enlarge the space. He worked with extreme skill and care and rescued a boy and attempted to rescue a man who was in an extremely difficult position. By this time Dandy had been working for approximately 40 minutes and was ordered to leave the cavity and come out for a rest. Marshall, relieving Dandy in the excavation, endeavoured to enlarge the cavity by working with additional jacks. He cut away timbers and floor joists, and removed a block of masonry which was holding down the casualty across the legs, by carefully breaking it to pieces with hammer and chisel. The man was rescued after two hours. Dr. Boul very courageously burrowed down under the wreckage with Garwood to render medical attention and remained under the debris until the last casualty was extricated. During this period he sustained the male victim who was lying face downwards almost in the fireplace, in which there was a fire smouldering, his legs being trapped by masses of masonry and timber. Dr. Boul supported him in this position throughout the two hours taken to carry out the rescue, subject all the time to falling debris and the danger of shifting wreckage.

Reports of Societies

EXFOLIATION OF BLADDER LINING

At the February meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland the President gave an account of complete exfoliation of the epithelial lining of the bladder in a patient aged 38 years. She had been married four years, and had had one previous pregnancy, which ended in abortion at 8 weeks in 1941.

On admission the patient appeared gravely ill, with a rapid weak pulse. There was a history of retention of urine with overflow for 14 days, and constipation for 21 days. The abdomen was distended and tender. Her last regular menstrual period had been in July (four months before admission), but her history was not very reliable. She had had some further vaginal haemorrhage in August. At the time of admission she had been bleeding slightly per vaginam for some four days, and was in great pain. About an hour later she gave birth to a foetus whose age was estimated at about 4½ months' gestation. The placenta followed rapidly. Bimanual examination disclosed a large solid mass filling the true pelvis and extending above it into the abdominal cavity. The cervix uteri was displaced upwards and backwards. The case was considered to be one in which a pregnancy had occurred in a large myomatous uterus. Subsequent events proved this diagnosis wrong. A catheter was passed and 14 oz. of foul bloody urine were withdrawn. A self-retaining catheter was introduced and left *in situ* for seven days. Her blood urea was 203 mg. per 100 c.cm. of blood. Her urinary output from the time of the introduction of the catheter was maintained between 40 oz. and 70 oz. a day. Her blood urea had fallen to 34 mg. per 100 c.cm. Progress was satisfactory after removal of the self-retaining catheter: occasional urinary stoppages were relieved by catheter. Three weeks after admission she complained of severe pain, and a dark-grey mass about 1½ in. thick protruded from the urethra, coming away easily with traction. It was a large portion of the epithelial lining of the bladder. After passage of this cast she was incontinent, but two months later had regained some control. Cystoscopic examination showed that not more than 1½ oz. of water could be retained in the bladder, which appeared to be lined with granulated tissue and bled very easily. Later examination showed some epithelial lining to be present. Bimanual vaginal examination disclosed a uterus normal in size; no evidence of tumour.

Dr. J. F. Cunningham said the condition was rare now, but used to occur more frequently. It occurred only in association with pregnancy. There was a gradual obliteration of the urethra, causing bladder distension with ischaemia and sloughing of the epithelial lining. Later, the bladder could be stretched so that normal function could be recovered.

Dr. J. S. Quin did not consider the condition was confined to pregnancy, nor did he agree with Dr. Cunningham that it was one of ischaemia, but rather one of acute infection of the bladder.

ARRHENOBLASTOMATA

The North of England Obstetrical and Gynaecological Society met on Jan. 19 for the first time since the outbreak of war. Prof. Farquhar Murray of Newcastle, the retiring president, introduced the new president, Dr. A. A. Gemmell of Liverpool.

Dr. C. P. Brentnall described a case of arrhenoblastoma of the ovary associated with pregnancy and labour.

There were no undue symptoms until the woman reached the fourth month of pregnancy, when evidence of virilism began to appear; masculine distribution of hair appeared on the abdomen, chest, and face; the voice became deeper and the clitoris enlarged. There were none of the usual defeminizing phenomena: the breasts, instead of atrophying, showed the usual changes associated with pregnancy, and the amenorrhoea of pregnancy could not be described as defeminizing. Glycosuria was constantly present—probably another case of the Achard-Tiers syndrome. The woman was delivered by Caesarean section, and the ovarian tumour removed under local analgesia. Lactation began and continued normally. The phenomena of virilism disappeared in six months after operation, except for the deeper voice. The child appeared to be normal except for the external genital organs. There was no doubt that she was a female pseudo-hermaphrodite. The clitoris was much enlarged, the labia majora were enlarged and corrugated. There were no labia minora, and no external entrance to the vagina. The urethral orifice was situated at the base of the clitoris, and the perineum extended unbroken to the anus. On the fourth day of life there came from the urethra the discharge of blood and mucus which is not uncommon from the vagina of newborn girls, and this was taken as a proof of the presence of a normal uterus. The methods of Nature and the laboratory in administering androgens to pregnant mammals were discussed. In this particular case it appeared, from evidence in the mother and child, that androgen from the ovarian tumour reached the child in effective quantity during the third month of foetal life, and resulted in the partial masculinization of the external genitalia.

Dr. J. W. A. Hunter described a case of arrhenoblastoma of the ovary.

The patient was a single girl aged 19. Her periods had begun at 11 years and were regular until she was about 15. At that time her voice became deep and her abdomen enlarged. Nine months later menstruation ceased and the breasts were reduced in size. Eighteen months after this hair appeared on the face, legs, and chest. She came to hospital because of the very marked increase in size of the abdomen. A hard tumour could be felt, reaching nearly to the xiphisternum. There was free fluid in the abdomen, and at the time of her admission to hospital she had a pleural effusion. A large tumour with an enormous blood supply was found when laparotomy was performed. It was removed with great difficulty. No metastases were seen. The patient's condition while in hospital was never good, and in spite of blood transfusion she died about 12 hours after the operation. Points of interest were the very large size for arrhenoblastoma, and its enormous adventitious blood supply.

Dr. J. W. Bride described another case of arrhenoblastoma of an immature type.

The patient was single, aged 32. She complained of menorrhagia for five or six months. Examination showed hirsutism, especially of the face, necessitating daily shaving. Intellect dull. There was a masculine distribution of hair on the abdomen. A hard mobile mass was palpable in the abdomen. The clitoris was greatly hypertrophied. Laparotomy showed a solid ovarian tumour about the size of a foetal head, and this was removed. Two years later the clitoris was much smaller, the hair on the face was much less, and she was only needing to shave once or twice a week. Her general health was good.

Adreno-genital Syndromes

Dr. A. A. Gemmell described a case of adreno-genital syndrome due to bilateral cortical hyperplasia of the adrenals.

The patient came complaining of primary amenorrhoea and some abnormality of the vulval region. She was of male configuration with no breast development, but had no facial hirsuties. Her voice was of female timbre and she had a normal feminine outlook. On examination under anaesthesia on April 26, 1944, the phallus was found to be 2 in. long, and no other abnormality was apparent. On May 5 Dr. Hain of Edinburgh estimated the ketosteroids as 35 mg. per 24 hours, and pregnanediol as 60 mg. per 24 hours. In June these had increased to 74 mg. of ketosteroids and 73 mg. of pregnanediol. On June 6 Mr. C. A. Wells amputated the phallus, and laparotomy was performed. The uterus was small and the ovaries appeared normal. Biopsy of the right ovary showed atretic and normal immature follicles and two large follicles and one with both granulosa and theca layers. Both adrenals were enlarged. A diagnosis of congenital bilateral suprarenal hypertrophy was made, and on the 27th Mr. Wells removed the left suprarenal by the transcostal route. It appeared elliptical in shape, and measured 3.5 in. by 2 in. by 0.5 in. It weighed 23 grammes after fixation. Vines's stain showed an androgenic reaction. There were no fuchsinophil cells in the outer zone. In the midzone 25% of the cells gave a positive stain, and less than 25% in the inner zone. The ketosteroid and pregnanediol levels fell to 32 and 31.5 mg. on estimation; they had risen again by Jan. 3. In December last menstruation had still not occurred, and there had been no enlargement of the uterus and no change in voice.

Mr. T. N. A. Jeffcoate described a case of adreno-genital syndrome due to an adenoma of the adrenal cortex.

The patient was a single woman, aged 30, complaining of primary amenorrhoea, and growth of hair on the cheeks, chin, and upper lip. The hirsuties had been present for 16 years, having gradually developed soon after the age of 14. She had a deep voice and a muscular and masculine figure with male distribution of hair. The breasts were undeveloped, and the nipples deeply pigmented. There were slight hypertrophy of the clitoris and a septate vagina with a hypoplastic cervix. Psychologically she was mainly feminine, interested in clothes and babies; sexually she was neutral. At laparotomy a tiny infantile uterus was found. The ovaries were pale, with numerous tiny cysts due to atretic follicles. Biopsy was performed to confirm that the glands were ovarian. The left suprarenal was felt to be larger than the right and appeared spherical. The patient recovered from the operation and later a ketosteroid secretion test was performed. The result of 140 mg. per 24 hours was the final link in the chain of evidence. Mr. C. A. Wells of Liverpool agreed to explore the left adrenal through the left loin three weeks after laparotomy. In the upper pole of the gland he found a rounded tumour which shelled out easily; and this was removed together with a small portion of normal tissue. About half the adrenal was left behind. The tumour, roughly ovoid in shape, was 2 in. in diameter, greenish purple in colour, dull red on section, owing to considerable extravasation of blood. Microscopically it was seen to be composed of cells recognizable as of adrenal origin. They showed a strong positive reaction to Vines's stain. Although at the time it was suggested by the pathologist that the tumour was of a low grade of malignancy, the patient was alive and well 2½ years later. The results of the removal were classical. Eight weeks after operation the patient menstruated for the first time, and had done so regularly since them. The uterus had grown to about normal adult size. After 2½ years the voice was unchanged, the clitoris unchanged, the breasts enlarged, and the skin of finer texture. The figure was slightly more feminine. The hair did not drop out dramatically as was often described, but was slowly becoming more feminine in distribution, and after electrolysis was showing diminished tendency to return. The ketosteroid excretion within one month of operation had dropped to 3 mg. in 24 hours. Psychologically she had become slightly more feminine, more modest, and less self-conscious.

The Whipps Cross Hospital Medical Society held a clinical meeting on March 9. The successful results obtained from the use of penicillin were demonstrated in a number of patients, including a case of interlobar empyema treated by aspiration and local application of penicillin, a cured case of staphylococcal septicaemia, an air-raid casualty who had sustained a ruptured liver, and a case of meningitis. A number of pathological specimens were also shown. The next meeting will be held on April 6 at 8.30 p.m., when Dr. Stanley White will show a film entitled "Sex Hormones: Physiology, Diagnosis, and Treatment."

The annual general meeting of the Society of Public Analysts and Other Analytical Chemists held on March 9 at Burlington House, London, marked the seventieth anniversary of the Society. It was reported that in the past year the usual activities had been maintained, the financial position remained very satisfactory, the membership had increased by 117 to 1,197, and the circulation of the Society's journal, the *Analyst*, in spite of paper restriction, had increased. There had also been important developments. In pursuance of the policy decided upon a year ago, the Society had formed, within the framework of its constitution, two groups concerned with particular branches of analysis—viz., the Microchemistry Group (chairman, Prof. H. V. A. Briscoe) and the Physical Methods Group (chairman, Mr. R. C. Chirnside). These groups will hold meetings from time to time in London and elsewhere. The proceedings ended with the presidential address of the retiring president, Mr. S. Ernest Melling, who, after reviewing some of the outstanding events of the past year in the Society's affairs, made some observations on the subject of water and water supplies. The address will be published in the *Analyst*.

Advisory Councils of Industrial Health are a recent development and are composed of members of employers' organizations, trades unions, and the medical profession. The object is to promote industrial health in the area concerned, making suitable reports and recommendations when indicated. The intention is for such a council to act as a single body, and not as an association of three types of representatives. The first such council was formed in Leeds two years ago. Another one was set up in Derby in March, 1944, and a further one in Burton-on-Trent in September, 1944. A joint meeting of these three councils was recently held in Derby, and representatives were invited from neighbouring towns where such councils are contemplated—Sheffield, Birmingham, Coventry, and Grantham taking part. Each of the existing councils described the work done and future work contemplated. Co-ordination and liaison between all such councils was arranged, and it was decided that the next joint conference be held in Derby in May, 1946. It is evident that the number of such councils will increase considerably, and that it will be only a matter of time before it is a national movement.

Correspondence

Estimation of Heat Radiation in Clinical Practice

SIR,—The article on "Estimation of Heat Radiation in Clinical Practice" by Drs. D. S. Evans and K. Mendelssohn (Dec. 23, 1944, p. 811) is important because it is in essence a plea for better scientific measurement of all physical radiations allowed to reach the body. The old adage, "To measure is to know," surely holds good in the case of radiant heat and infrared, as in the case of *x* rays or radium or other physical influences brought to bear upon patients.

There is, however, one point that is overlooked in this article which is of considerable clinical importance, and that is, that the great majority of cases treated by infra-red or radiant heat have interposed between their skins and the source of heat either a single piece of lint or a sheet or towel. It would have been of great interest to have known what difference in wavelength is effected by such a procedure.

The majority of patients that attend at my rheumatic clinics have been treated during part of their illness by radiant heat and massage or infra-red and massage. In a small percentage of these cases the patient asserts that considerable benefit was derived; but there is never any evidence of any clinical details of technique, as to how the radiant heat or infra-red was given.

That radiant heat or infra-red can be potent for harm has been shown decisively during the war in the treatment of shock and similar conditions. In a survey of a number of Air Force stations receiving wounded, crashed, and shocked patients, there was unanimity of opinion that a very small quantity of radiant heat did good, that it did more good when the patient was treated in his flying clothes, and that if the radiant heat was left on for any length of time its effect was rapidly harmful. It would seem that the patient's clothes prevented any considerable quantity of ray energy reaching the body; and the short time enabled the clothing to be warmed without becoming a source of radiating energy. As a result, the body-envelope of air is heated by conduction and convection.

On the strength of these observations the R.A.F. Electro-Medical Research Unit developed a means of conveying air slowly and smoothly at varying temperatures, free from direct radiation, to the patient, so that he can be subjected to a simple form of air conditioning.

Investigations are proceeding on these lines. In the meantime a warm welcome should be given to every effort to make accurate measurements of physiotherapy methods when applied to the body.—I am, etc.,

London, W.1. C. B. HEALD.

Ovariotomy or Caesarean Section?

SIR,—Prof. S. J. Cameron (March 3, p. 307) has invited opinions from his colleagues on their methods of dealing with ovarian cysts in pregnancy. Here is the experience and practice of one whose opportunities must have fallen far short of his own. First the experience: (1) several ovariotomies (the exact number is not readily available) performed between the 16th and 32nd weeks of pregnancy; (2) three ovariotomies during the early puerperium—two on account of twisting of the pedicle, the other because of infection in the cyst; (3) five ovariotomies and Caesarean sections in women near term or in labour.

No one will seriously challenge ovariotomy in groups (1) and (2), even if, as in many cases, the cysts are symptomless when first discovered. Torsion of the pedicle is more frequent in pregnancy (20%) and the puerperium (40%), the cyst if it is pelvic will offer an obstruction in labour, and, finally, we can never be happy about an ovarian tumour until it is excised and sections have been examined. It is the third group around which discussion will develop. In four patients the dermoid cysts were pelvic (obstructive), and in three of these the patients were in labour and the cervix was fully dilated. Forced down by strong pains and the presenting part, the bulging tumour and overlying vaginal wall were visible just within the vulva in two of these patients. One cyst was found to be firmly adherent to the floor of the pouch of Douglas. The fifth tumour was a multilocular cystadenoma and was situated in the left hypochondrium (non-obstructive).

I have based my practice of first performing Caesarean section and then ovariotomy on the following grounds: (1) Considerable forward dislocation of the pregnant uterus or even complete eventration may be necessary before obstructive cysts can be delivered if manipulations are to preserve the integrity of the cyst wall and safeguard the thin-walled veins in its pedicle. (2) Some cysts may be adherent, and the difficulties and dangers of delivering them from behind the pregnant uterus are even more pronounced. (3) After evacuation of the uterus there is a marked decrease in the calibre of the veins of the pedicle; this is easily ligated, and as a result of the relaxation of the broad ligaments can be buried without drawing structures together under tension. (4) Only one anaesthetic is necessary, which may not be so unless the condition of the cervix is such as to justify immediate vaginal delivery. (5) The lower-segment operation is always used, the risk of subsequent rupture of the scar is very remote, and there is no question of condemning these women to a series of repeat operations. In one of my cases of obstructive cysts the patient was not in labour. By adding abdominal delivery to ovariotomy such a course seemed at least more humane, and under modern conditions and with present-day technique the maternal risk can have been increased by only an infinitesimal degree.

It must, however, be admitted that there are arguments on the other side. One can readily imagine that in an occasional obstructive case in which, from repeated vaginal examinations or from other interference, infection may be presumed or is clearly evident, the cyst might be drawn out of the pelvis and the infant delivered either by version or by forceps with advantage to the mother. This could be done by an assistant while the abdomen was open, the ovariotomy then carried out, and the pedicle dealt with under the most favourable technical conditions. The older vaginal methods of dealing with obstructive cysts carry too many risks to warrant them any place to-day outside the history of obstetrics.

In the latter part of his letter Prof. Cameron has raised another subject when he avows his belief that the classical should be selected in preference to the lower-segment operation in cases of placenta praevia. In 1932 I performed the first lower-segment operation for placenta praevia in the Liverpool Maternity Hospital, and three years later began to carry out this procedure in such patients under local analgesia. I published in 1939 the details of my first forty-three patients, and since then this number has been considerably added to, still without maternal mortality. In the same publication I considered fully the arguments against the lower operation; indeed I set them out so fairly and prominently that several people have confessed that, on reading this section, they were deterred once and for all from ever using this method in cases of placenta praevia. In fact, most of the arguments were the conjectural outpourings of theoretical minds, and in actual practice it was found that things just did not work out in the way that had been supposed. The literature shows quite clearly that the majority of those who use the lower-segment operation as their standard procedure also employ it without demur in their patients with placenta praevia. It shows, too, that the maternal mortality of this operation in placenta praevia is certainly not higher than the classical.

Since 1932, 175 patients with placenta praevia have been delivered through the lower segment. In ninety-seven patients local analgesia was used. There were three deaths, none in the last 100—post-partum haemorrhage (spinal anaesthesia), diabetic coma (general anaesthesia), peritonitis (general anaesthesia, intrapartum infection with rigors at time of operation). Local analgesia is invaluable as our chief means of preventing uterine atony and post-partum haemorrhage; ergometrine and pituitrin act swiftly and powerfully without first having to overcome the relaxing effects of general anaesthesia. Since the beginning of 1942 there have been fifty-one abdominal deliveries, all but two by the lower-segment operation, and in thirty-one of these the anaesthesia was local. So it would seem that a certain uniformity of practice exists in this hospital, whenever abdominal delivery is selected as the method of treating cases of placenta praevia.

But these perhaps are not the most important things after all. It is evident from the closing part of his letter that Prof. Cameron and I are in full agreement on the main issues. With the lavish use of blood and plasma, anaesthesia carefully chosen and carefully administered, courage, energy, and operative ability on the part of the obstetrician, no exsanguinated woman should die if she once gets as far as a bed in a well-equipped and well-staffed maternity hospital. Bed is enough, for, as he obviously and rightly implies, mere transference to the theatre table may gravely jeopardize the chances of such women.—I am, etc.,

Liverpool. C. McINTOSH MARSHALL.

Sulphonamide Therapy in Otitis Media

SIR,—Nine months ago I drew attention in the *Journal* (June 3, 1944, p. 747) to some of the dangers attributable to sulphonamide therapy in suppurative conditions of the middle ear and mastoid, and in the intracranial complications arising therefrom. The article stimulated a correspondence which continued for many weeks, but some widely divergent views were expressed, and as a result no unanimity of opinion emerged to act as a guide in assessing the need for using these drugs in otitic infections.

Some correspondents supported the free, if not indiscriminate, use of these drugs both before and after drainage, and denied that masking of symptoms occurred as a result of sulphonamide therapy. Such views are in direct conflict with those expressed last week at a representative meeting of otologists in London, at which this subject was under discussion. Stronger views than were contained in my article in condemnation of the indiscriminate use of these drugs were expressed by many speakers, and much emphasis was laid upon the masking effect and also upon the deafness which can result from the action of sulphonamides. Sensitization of the patient, rendering him drug-fast, and damage to the kidney were also factors causing disquiet. In the milder forms of acute otitis it is probable that resolution would be just as complete, and in some cases with better hearing, if the drugs were withheld.

Now that a sufficient time has elapsed since the introduction of sulphonamides to enable observers to take stock and assess both the value and danger of these drugs in otitis, it would be useful if a clear expression of opinion from otologists were available to those who feel uncertain about the indications for the use of such a two-edged weapon in cases of otitis media.—I am, etc.,

London, W.1. A. R. DINGLEY.

Trichlorethylene in Midwifery

SIR,—I do not remember seeing an adverse report on the use of trichlorethylene as an analgesic in midwifery. Freedman (*Lancet*, 1943, **2**, 696) using his inhaler and Edwards (*Brit. med. J.*, 1943, **2**, 795) using Marrett's inhaler were satisfied as to its efficiency and relative safety.

I have been using it for some years, and believe it to be superior to nitrous oxide in many respects. I have noted no undesirable effects. Originally I used an inhaler of the draw-over type, which I designed and had made, but I found this somewhat clumsy. It occurred to me that the old-fashioned Clover or Hewitt's modification would possibly answer the purpose.

This I have found to be the case, and in the last 40 or 50 cases in which I have used it I have been well satisfied with the results. My practice is to place about 1 oz. in the container, to remove the rebreathing bag, and to fix the indicator at between the 1/4 and 1/2 positions, with a small piece of rubber tubing compressed to go between the container and indicator.

The patient uses the inhaler herself in the same manner that she uses a nitrous-oxide-and-air machine. As the head is crowned and when delivery is taking place the indicator can be moved to "Full on." If trichlorethylene is administered with the indicator in this position for some minutes perineal repairs can be carried out, although the patient will not be relaxed. It is my belief that the fact that trichlorethylene does not cause muscular relaxation is of definite advantage in midwifery, since the uterine tone seems to be maintained. This is, of course, a property of nitrous oxide, but trichlorethylene has the obvious advantages of portability and cheapness.—I am, etc.,

Mount Vernon Hospital, Northwood. D. C. DEVITT.

Barotrauma

SIR,—The following facts regarding the history of aviation medicine of the ear may be of interest in view of the letter by Mr. F. W. Watkyn-Thomas (March 3, p. 310).

The earliest account of aural symptoms caused by flying was given in *1783* by Charles—a French physicist. He invented the hydrogen-filled balloon, and during his first flight to over 1,500 fathoms—i.e., over 9,000 ft.—he apparently suffered from a mild anoxaemia from which he was roused by severe pain in his right ear and "glandes maxillaires." Charles attributed the earache to expansion of the air within the cavities of the ear during ascent.

As a result of the study of the symptoms experienced by Charles and by many other balloonists and of his own observations in the decompression chamber, Paul Bert wrote the following comprehensive account of the effects of barotrauma on the ear in *La Pression Barométrique,* which was published in *1878*:

> "Pains in the ears have been noted by all observers during compression as well as decompression. All have given the exact explanation of them; they have shown that since the Eustachian tube, obstructed for different reasons, does not permit the compressed air—i.e., during descent—to enter the tympanic cavity, the tympanic membrane is pushed back and distended, causing pain which may be unendurable. Sometimes it is even ruptured. . . . Similar symptoms, but less severe, accompany decompression (i.e., during ascent). They can be checked by opening the tube, either by swallowing or—and this is a more certain method—by making a strong expiration with the nose and mouth closed. These repeated procedures result in re-establishing the permeability of the tube, the obliteration of which is a frequent cause of deafness. . . ." (Hitchcock's translation, 1943.)

In *1918,* at the request of the military authorities, Mr. Sydney Scott visited France to investigate the aural disabilities which were occurring in flying personnel. As a result of his observations he formulated a series of rules (published in 1919), of which the following form a substantial part of the prophylactic measures adopted to-day to prevent barotraumatic disabilities:

> "(*a*) Airmen should not fly with a cold in the head or sore throat, or when unable to inflate both Eustachian tubes at will.
>
> (*b*) Airmen who can open the Eustachian tubes by swallowing should use chewing-gum to stimulate the flow of saliva and keep on swallowing—especially during descent.
>
> (*c*) Airmen who cannot rely on swallowing to open the Eustachian tubes repeatedly and rapidly should make a rule of self-inflating the ears by Valsalva's method and should begin to do so at the commencement of descent—repeating the procedure once, say, every 1,000 ft.—and not wait until they land."

It was not until *1937,* however, that the signs and symptoms of tubal dysfunction during flight were described as an *entity* by Armstrong and Heim, and they designated the syndrome "aero-otitis media."—I am, etc., JOHN E. G. MCGIBBON.

SIR,—Your correspondent Dr. A. B. Alexander (Feb. 24, p. 276) brings up the difficult question of the nomenclature of otitic barotrauma. This has been the subject of much discussion among interested Service otologists, both British and American. The term "otitis media" at once calls to mind an infective lesion of the middle ear, and the prefix "aero" does not dispel this. We agree that inflammation is an inevitable sequel of the trauma, and therefore have no objection to the implication of inflammation suggested by the adjective otitic. The only non-inflammatory change that can be seen on otoscopy is the inward displacement of the membrane: all other visible changes are inflammatory. Thus "otitic" is, in our opinion, the correct adjective, as it gives the correct geographical site of the lesion and also implies the secondary inflammatory changes.

We consider that the condition is essentially traumatic, and do not think that the term "barotrauma" is in any way misleading. The tympanic membrane ruptured by atmospheric pressure is just as much an injury or trauma as the lung ruptured by oxygen delivered from a cylinder, and few would dispute the traumatic nature of the latter.

"Tubo-tympanic pressure syndrome" is a cumbrous term which is not self-explanatory. No satisfactory reason for its adoption has yet come to our notice, and until some adequate reason for changing the nomenclature is brought forward we propose to continue to call the series of changes produced by atmospheric pressure in an unventilated middle ear "otitic barotrauma."—I am, etc., E. D. DALZIEL DICKSON,

Central Medical Establishment, R.A.F. Air Cdre., R.A.F.

The Medical Film

SIR,—Your leader of Jan. 20 (p. 87) on the medical film has just reached me. It is so much to the point that I feel disposed to add to it.

Some ten years ago a small party, including myself, convinced of the value of the film as an instrument of education, and having suffered as students from some of its early and boring misapplications, began to produce surgical teaching films, with the support of several of the senior honorary members of the staffs of the Manchester Royal Infirmary and Salford Royal Hospital. Production ceased at the outbreak of war for obvious reasons, but by that time a number of films had been made (including one which was awarded the Bronze Plaque of the Royal Photographic Society), and we were agreed on certain basic principles governing the technique of the film in medical teaching.

The present-day student audience is fundamentally a section of the ordinary film-going public which by long use has come to accept nothing short of perfection in photographic and cinematic technique. Therefore, the slightest suggestion of "amateurishness"—whether in photography, lighting, cutting, or continuity—is immediately recognized, and not only excites adverse comment but diverts the student's attention from the real purpose of the film. It is not enough merely to photograph an operation and screen the result. Weeks of preliminary work are required, and the script must be as finished as for any entertainment film. Cutting and timing after shooting are as essential in teaching medicine as they are in a Hollywood "musical," and a film that takes days to shoot may take months to cut.

The ideal medical production unit is built round the professional side, and not vice versa. We were fortunate in finding the whole team—cameramen, lighting technicians, cutter, and so on—from those who were either qualified or at least final-year students. In the majority of cases the senior "honorary" who "sponsored" the film decided the general line to be taken, and thenceforth acted as adviser rather than as director, as this latter job demands a degree of technical knowledge of the cinema which is rarely coupled with professional eminence. The technicians were found among the younger members. A wholly professional team makes for very smooth working, especially in the operating theatre, where the presence of laymen is always a handicap and may be a danger.

The Manchester Unit consider that the film should be used as a supplement to clinical teaching, and that its use in such a way, like the summary at the end of a chapter, can be instrumental in clarifying the student's ideas. It cannot replace actual clinical instruction in the infinite variety of cases (although its limited value in this respect is discussed below), for by its very nature the film must be dogmatic. Technically, first-rate colour is essential, and this demands skilled photographers. The value of sound is debatable. At present sound projectors are rarities in medical schools, and in any case the "summary" film is often better for the skilful use of silent titling and cartoon. Visual memory in most of us is more reliable than auditory.

The film has other more specialized applications. It is an ideal instrument for teaching the principles of operative technique, since intelligent camera work can put every member of a large class in the position of the surgeon or at least of the first assistant—a marked improvement on the usual unseeing huddle of students at an actual operation. Long-focus lenses bring the finest detail into satisfying close-up. In passing, few surgeons operate easily for the camera without practice. Hands must be kept out of the "line of fire," even at the cost of some discomfort.

The third great use of film—that which your leader refers to as "Prof. X's series of films of tics and tremors"—requires different handling. Here we feel that individual case films, indexed like ordinary case notes, should be available centrally to illustrate actual cases. A lead title and catalogue number should identify them, and printed notes should be available for the teacher. They should remain silent, and be used exactly as the present-day lecturer uses an actual patient for demonstration. In effect they constitute a series of selected patients, untiring, and constantly "on tap" at all stages of their disease. Such film-strips—they are not true films—can be assembled as required, with a few feet of black spacer-strip between cases, and the projector used to run each case through, stopping on the spacer until the next case is required. We used this method for Mr. Robert Ollerenshaw's presidential address to the Orthopaedic Section of the R.S.M. a few years before the war to demonstrate in London a series of patients who lived in the North and who were therefore not available for the meeting.

Finally, I can confirm from my own experience, both in the Service and before, the efficiency of the film as an instrument of education. But it must be properly used, otherwise we shall build up a barrier of conservative opposition to this development from people who say that the film is no good, but who really mean that *bad* films are no good. The Scientific Film Association may be "interested in means rather than ends," but unless the means be skilfully handled the end will not be achieved. Perhaps the formation of a Section of Medical Cinematography of the R.S.M. may be the answer.

My apologies are due to the other members of the team for not consulting them, but they are scattered over various theatres of war. I trust they will not think I have misrepresented them.—I am, etc.,

ROBERT G. W. OLLERENSHAW,
C.M.F. Major, R.A.M.C.

Nursing and Tuberculosis

SIR,—The grave responsibility of nurses' health does not seem to be anyone's business. Your medical correspondents look at the case from the point of view of infection. The letter from J. Eyre (March 10, p. 345) sets out, more ably, the whole picture.

Infection is only part of the problem. The maintenance of resistance is highly important. The factors which contribute to breakdown in health often form the environment in which the average nurse must live and work during training. Her span of day is long—13 and sometimes 14 hours. Her working week is at least 48 hours, often longer, and in addition she is the servant of an examining body. Meals are frequently badly spaced, so that she works hard at high pressure when hungry and tired.

At one time the nurse in training was called a probationer; now she is designated "student nurse," but the status has not been changed. Sister tutors have been appointed to help her. It is their heartbreak to see, more intimately than others, these young girls of all classes, arriving keen and anxious to serve, become discouraged and disheartened: discouraged by the double burden of work and study far too great for anyone to carry for long, and disheartened because they are not taught at the bedside. To the medical men they are only the "hewers of wood and drawers of water," and as for the busy ward sister she is first of all a foreman and must get the work done. She is interested and would teach if she had time, but there is no time.

The bookstalls display considerable literature on health care. Our young people come to hospital to learn how to put this into practice, only to find they must make bricks without straw; the tools are not provided; and, moreover, they may be expected to live and work under sordid unhygienic conditions that would not be tolerated in the homes from which they come.

Supervision of nurses' health has been dealt with in a pamphlet issued by the King's Fund. And yet we find raw recruits to sanatorium nursing sent on duty without any instruction on the precautions to be taken to prevent the spread of infection and safeguard their own health. They may be given an initial medical examination with *x*-ray examination of the chest, or this may be deferred for several weeks. Up to the present this recommended measure is not made a condition of recognition of nurses' training schools, not even of sanatoria. When a nurse becomes liable to "direction" under the Ministry of Labour regulations an initial medical examination, including *x*-ray examination of chest, is required before she is permitted to nurse cases of pulmonary tuberculosis. A nurse becomes liable to "direction" when she has had 12 months' nursing experience. It is evident, therefore, that what is the right of the worker of 12 months' experience is not demanded for the raw recruit who enters a sanatorium for training.

Your correspondent is right: "make do and mend" have reached saturation point. An entirely new approach to the training of nurses is needed if *nursing* is to survive.—I am, etc.,

London, W.2. EVELYN C. PEARCE.

Penicillin: Price and Manufacture

SIR,—I am very much obliged to Dr. Frank Hartley for his instructive letter (March 3, p. 307) on the subject of the price of penicillin. Even now, however, we have not been told what the price of penicillin is or why there is any need to make a secret of it. What exactly does Dr. Hartley mean by saying that the rumoured price is in excess of the real one by 1,000%? Does he mean ten times as much? If so, I can only imagine that the 1,000 was used to make the figures more impressive, like expressing a mile in terms of millimetres.

I think Dr. Hartley need hardly be surprised that there is still a widespread impression in the public mind that there is a "penicillin ring." I can't quote chapter and verse, but the impression was surely launched by the Minister of Health in the House when he stated that the manufacture was to be given over to one or two large firms, as only these would be efficient enough. It was as a result of this statement that most of us who were already making the stuff decided to "pipe down." Now it appears that, apart from any ordinary trade associations, the firms in question are welded together by the Therapeutic Research Corporation, of which Dr. Hartley is secretary. It is surely asking too much to expect the public to believe that such an organization has never discussed the question of price.

It is good, however, to hear that some competition is at last being permitted, but it is very hard to see why this was not encouraged from the first. There are surely ample safeguards in the law as it stands to ensure that bad stuff is not sold to the public, and it is merely ridiculous to restrict the manufacture and then subsequently announce that there is none for general public use. One gets an uncomfortable feeling that this is a highly characteristic piece of bureaucratic interference which augurs ill for the future of medicine.

I hope someone will tell us what is done with "time-expired" penicillin. I know of one large hospital where it is all destroyed on the day of expiry, but is it, in actual fact, any the worse for being time-expired if kept in refrigerator?—I am, etc.,

Haywards Heath. J. W. SHACKLE.

The Metric System and Medicine

SIR,—By the time this letter reaches you there may have been further correspondence of which I am unaware. Some of your correspondents have rightly stressed the danger of using dual mensurations. In a recent medical article one found the abbreviations "g., gr., gm."—small wonder that one of my assistants needed my help in their interpretation. Again, in a modern obstetric textbook appears "cm." and "in.," in the same paragraph and separated by only a few lines. Since Sir John Anderson has given an emphatic "no" to the question of adoption of the metric system in Britain, and since there seems to be no doubt that our obsolete and complicated method of weighing and measuring is to be perpetuated for generations to come, I should like to make a final plea. In all medical articles and books might the metric equivalents be put in parenthesis? Especially does this apply to prescriptions. I can assure those authors who take the trouble to do this that they would receive the silent thanks of the many foreign doctors who wish to read British medical publications.—I am, etc.,

Istanbul University. W. C. W. NIXON.

Child Guidance Clinics

SIR,—Without wishing to express disagreement with the main argument of Dr. Ralph A. Noble's letter (March 10, p. 345), there are certain statements of fact in relation to child guidance clinics which require correction. In the explanation of the grouping of the clinics set out in the list prepared by this Council it is expressly stated that "owing to difficulties of staffing it has now been decided that newly established clinics and clinics where there have been changes of staff should remain unclassified until after the war." Consequently the 15 listed as Group 1 Clinics are those which were in existence at the outbreak of war and where no changes of staff have occurred since. The facts are that 47 clinics are fully staffed—i.e., with a complete team of psychiatrist, psychologist, and psychiatric social worker—and only 3 not under medical direction (a comparative table is given in the report of the Provisional National Council for Mental Health for 1943). Some of the clinics are under the administrative direction of a school medical officer who is directly responsible to the Education Committee. But in the great majority the psychiatrist is responsible for clinical direction. The Council has from its inception done its utmost to ensure that child guidance work in this country shall be carried out by fully staffed clinics under psychiatric direction, and has always had the fullest co-operation in attaining this objective from the Ministries concerned.—We are, etc.,

Alan Maberly,
R. G. Gordon.
Medical Directors, Child Guidance Council.

The Services

Col. E. A. Sutton, C.B.E., M.C., late R.A.M.C., has been appointed D.D.M.S., and has been granted the acting rank of Major-Gen.

Temp. Surg. Lieut.-Cmdr. R. St. J. R. Johnston, R.N.V.R., has been mentioned in dispatches for outstanding courage, leadership, and skill during the build-up of the Normandy bridgehead.

Capts. P. Delap and L. F. McWilliams, R.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in the field.

The *London Gazette* has announced the appointment as M.B.E. (Military Division) of Fl. Lieut. R. C. Dickson, R.A.F.V.R. The citation reads as follows:

> One afternoon in November, 1944, an aircraft landed from an operational sortie, but when it had proceeded some 600 yards up the runway an explosion occurred and the aircraft burst into flames. Fl. Lieut. Dickson, the medical officer of the unit, immediately hastened to the scene and, on arrival, found one member of the crew lying clear of the wreckage. After giving this airman a cursory examination, Fl. Lieut. Dickson gave instructions for him to be removed to hospital immediately. By this time ammunition and pyrotechnics in the aircraft were exploding continuously. The petrol tanks were blazing furiously and liable to explode at any moment. Undeterred, Fl. Lieut. Dickson went to the aircraft to help another member of the crew who was trapped in the burning geodetics, his boots being on fire. Displaying complete disregard for his own safety, Fl. Lieut. Dickson tore away the geodetics with his bare hands, injuring himself in the process, and freed the airman, whom he then dragged to safety. Fl. Lieut. Dickson's courage and devotion to duty on this occasion undoubtedly saved two lives. He has at all times shown outstanding devotion to duty and has done much to maintain the morale of air crews and ground personnel during difficult periods.

DENTAL UNITS FOR THE NAVY

At the Royal College of Surgeons on March 8 two Red Cross and St. John Dental Units were presented by Field-Marshal Sir Philip Chetwode, on behalf of the Joint War Organization, to the Admiralty for the use of the Royal Navy. Sir Alfred Webb-Johnson, President of the College, who was accompanied by the Vice-Presidents (Sir Girling Ball and Mr. C. Max Page) and the members of the Council, said it was a happy idea to hold this ceremony at the Royal College of Surgeons because it could be regarded as the academic headquarters of British dental surgery. By far the greatest number of dental surgeons practising in this country were licentiates of the College, which was also the home of the finest Odontological Museum in the world. The fullest advantage could be obtained from this gift only if adequate numbers of skilled technical assistants were provided to help in the dental service. The accepted policy of the College was that dental surgeons, particularly those in public services, should be relieved of much of the details of dental prosthetics and of routine oral hygiene, which should, however, be carried out under their direction. The provision of an adequate number of technical assistants would leave the dental surgeons much more time for real operative dental surgery and for scientific work. It was in communities like schools, factories, and the Services that this work could be organized most efficiently and the greatest benefit result for the greatest number. An example had been set by the Royal Air Force, and he trusted that the Royal Navy would adopt the same plan. Sir Philip Chetwode said that the Red Cross and St. John were happy to hand over these units to the Navy. Surg. Vice-Admiral Sir Sheldon Dudley, Medical Director-General of the Royal Navy, in accepting the units with gratitude, said that he could testify to the celerity with which Red Cross and St. John answered an appeal for help.

Obituary

R. M. DOWNES, C.M.G., M.S., F.R.A.C.S.

Major-General, Australian Army Medical Services

It is now known that Major-Gen. R. M. Downes, war historian, Australian Medical Services, and Major-Gen. G. A. Vasey were killed in an aeroplane accident which occurred off the North Queensland coast on March 5. The Commonwealth Prime Minister, Mr. Curtin, who announced the accident, said it was a shocking blow to Australia.

Rupert Major Downes was born at Adelaide on Feb. 10, 1885, son of the late Major-Gen. M. F. Downes, of Dedham, Essex, and of Brighton, Victoria. He was educated in England at Haileybury College and in Australia at Ormond College, and entered Melbourne University as a medical student, graduating M.B., B.S., and eventually taking the M.D. and M.S. degrees. He joined the A.A.M.C. in 1908 and served during the last war with the A.I.F. In 1916–17 he was A.D.M.S., Anzac Mounted Division, and during the next two years held the post of D.D.M.S., Desert Mounted Corps and A.I.F. in Egypt. He was mentioned in dispatches and created C.M.G. in 1917. He served for thirteen years after the last war as D.D.M.S., 3rd Military District, and Director-General of the Commonwealth Medical Services, with the rank of major-general, from 1934 until last year, when he relinquished that post and was made medical historian to the Australian Army.

Gen. Downes had been consulting surgeon to the Children's Hospital, Melbourne, and the Victoria Eye and Ear Hospital, lecturer on medical ethics in Melbourne University, and honorary surgeon to the Governor-General of Australia, 1927–31. He became a Foundation Fellow of the Royal Australasian College of Surgeons in 1926. He joined the B.M.A. in 1911, was president of the Victorian Branch in 1935–6, and represented his Branch at the Aberdeen Meeting just before the outbreak of this war. The sympathy of the profession of this country goes out to their colleagues in Australia and to the widow and children of a very distinguished public servant.

HAROLD CHAPPLE, M.Ch., F.R.C.S., F.R.C.O.G.

We regret to announce the death at his home in London on March 8 of Mr. Harold Chapple, senior obstetric surgeon to Guy's Hospital. Following an illness in January he had just begun to work again when he collapsed in his consulting-room, and after only two days' illness he died.

Chapple was born in Australia on Feb. 13, 1881, and took his B.Sc.Adelaide before coming to this country; the result was that he started medicine rather later than most. He studied first at Cambridge and then in 1905 went to Guy's for his clinical work. He qualified M.B., B.Ch. in 1908. In 1910 he became F.R.C.S.Eng., and in 1911 M.Ch. After two years as registrar he was appointed obstetric surgeon to Guy's Hospital in 1913 on the death of Mr. Targett, and apart from the time that he spent in the R.A.M.C. during the war 1914–18, he continued to work there until the time of his death.

J. B. B. writes:

In his earlier years he was joint author of two textbooks, and from time to time he contributed to the journals, but it was not on the academic side that Chapple was outstanding; rather it was in his approach to the practice of his specialty. All his life he insisted on treating the patient as a patient, and no one was more aware of the psychological aspects of gynaecology. Above all, however, he was masterly in his handling of the apprehensive patient and the difficult patient, and he was able to inspire the greatest confidence in all. As a surgeon he was always thoughtful and painstaking, obtaining excellent results in consequence. His charm of manner and extreme courtesy were notable in his dealings not only with patients but also with junior colleagues, nurses, and students alike. He was more observant, however, than many realized, and those who were poor at their work were soon recognized. Even up to a short time before his death he would assist a new registrar with an operation and remain patient to the end, however slow the operator might be. His patience and calm were really quite extraordinary, but it was curious to realize that with the outward calm and unruffled manner Chapple was sometimes worrying about a patient, and worrying to excess.

As a young man at Guy's Chapple was renowned for his vigorous enjoyment of life and his many accomplishments. He was an excellent games player, getting equal pleasure whether winning or losing. While at Cambridge he won his blue for tennis, playing in a famous six which included Wilding. In addition he played rugger, swam, sang, and was a really good actor. Up till recent years he made golf his recreation and often played for the Medical Golfing Society. In 1939 he was elected president of the society, and remained so until he died. On golfing occasions, and indeed on many others, he was most excellent company, whether host or guest, and he excelled as a raconteur.

In 1938 Chapple was taken suddenly ill one evening in his consulting-room and for several days was near dying from a coronary thrombosis; he was always sure, however, that he would recover, and eventually he did, to start work again some six months later. It was from this time that one realized the courage that he possessed; even when most ill he could still joke, and ever afterwards he would never let his disability damp his zest for life. In 1940 when he should normally have retired from Guy's he chose to carry on, and regularly twice a week he journeyed to Pembury to teach Guy's students and to operate. He felt strongly about the war and the necessity to do a job of work so long as Britain and the Empire were engaged in a deadly struggle for life. For many years he had talked of the danger inherent in the German way of thought and life, and for long had foreseen this war. His loyalty to this country was only equalled by his love for his native country: he was always proud of being an Australian, and this would show in little ways—for example, his affection for the blue of the R.A.A.F. His was a lovable spirit and he will be sadly missed by many friends. In 1911 he married Irene, daughter of Sir William Arbuthnot Lane. To her and to their two sons we extend our deep sympathy.

D. M. MacM. sends the following tribute:

I have been asked to write an appreciation of my dear friend, Harold Chapple. I would epitomize his character in three words—charm, courtesy, and consideration. To few men has it fallen to be so beloved not only by their patients but by all with whom they have worked—sisters, nurses, students, and doctors. Harold loved life, loved his work and all humanity. He often said to me: "How lucky you are to have all types of patients—whereas I deal only with women." Loving his chosen branch of our profession as he did, yet he was essentially a man's man, a tennis blue, a good golfer and good companion. In his work he was of the very best: a first-class accoucher with (as he expressed it) a niblick in his bag to get out of the bunkers with which maternity abounds; as a surgeon a first-class operator. His plastic perineorrhaphies were truly brilliant and brought years of good health to very many women who had endured previous years of constant suffering. In over 30 years of helping him operate I have never known him lose either his temper or his nerve in the theatre no matter what crisis may have arisen; no wonder the theatre sisters and nurses loved to work for him. As a teacher he was exceptional. He loved the young and they in return venerated him: one of his most valued possessions was a signed photograph of himself and a class of students with the proud caption of "Pass list 100%." But my happiest memories are away from work—on the golf course and around the table—a wonderful host and a wonderful pal, witty, charming, and entertaining. He died, as he would have wished, in harness, helping others to the very end, and with his passing leaves a gap that it is impossible to fill—loved and missed by his friends and patients both in the Borough and in the more stately homes of the West End.

LORD DAWSON OF PENN

Lord Moran, P.R.C.P., sends the following tribute, which appeared in the *Sunday Times*:

It will be a long time before any member of the medical profession will again influence opinion in England as Lord Dawson did between the two wars. I am not sure that I can explain this to those who did not know him. He stood apart from others, not so much for his pre-eminence as a physician, but rather because he possessed a gift which is more prized than any other by men of affairs: he knew instinctively what the average man was thinking and how he would react to some measure or action that had been taken by the official world. He was, of course, born with that gift, but he had developed and perfected it over the years until his judgment in such matters was impressive. This almost intuitive knowledge of what was happening in men's minds contributed to his success in practice—and no doctor in his time was more successful. Once when I had seen a patient with him and we had to explain to half a dozen relatives the gravity of the complaint, he appeared to divine at once what was passing through their minds, and he was able to quieten their fears in turn before they had even found expression.

Like his Royal patient, King Edward VII, Lord Dawson was more interested in men than in books. He learned from experience, so that he had come to have a profound knowledge of the ways of men. His name was a household word for two generations; all the prizes that the world can give were his. Great professional success makes day of night, but he never hurried over anything, and he gave as much care to the humblest commoner as to the King of England.

He was quite unspoiled by success, and never lost his curiosity in young people. He spoke to them as one of themselves, and they opened their hearts to him. Lord Dawson himself seemed until quite lately to be untouched by time. His eager spirit continued to regard life as great fun; it was still an adventure that had not lost its freshness. In mind and body he remained alert; even in going upstairs he would take two steps at a time. Then came distressing illness. He wrote to me after his first operation: "So far so good, but not very far." And after the second and more serious operation he remained undefeated. He insisted on being kept in touch with affairs, and one of those summoned to his bedside has told me that it was an hour and a half before he was allowed to depart. He had enjoyed a strenuous life, and now he was resolved to go on working to the end.

Sir Frederick Menzies writes:

I should like to be allowed to pay my humble tribute to the memory of Lord Dawson of Penn. Although I knew him slightly before the war began in 1914 it was not until the year 1919 that our acquaintance gradually developed into a real friendship. This was mainly due to the fact that very soon after Dawson returned from war service it became obvious to me that he was one of the first of the eminent members of our profession to appreciate the great developments which were then rapidly taking place in the work of the Public Health Services, notably in connexion with tuberculosis, maternity and child welfare, venereal diseases, and the school medical services, and the still greater developments which were likely to arise in the near future as a result of the report of the Maclean Committee on Poor Law Reform. In these and in many other directions Dawson saw far ahead of many of his contemporaries in voluntary hospital circles, more especially because he fully realized the effect which these responsibilities, placed by Parliament upon local government authorities, must have upon the future relation between voluntary hospitals, particularly medical school hospitals, and the local government authorities throughout the length and breadth of the whole country. From 1919 to 1939 Dawson never ceased to work hard towards the greatest measure of harmonious co-operation possible between the voluntary hospital organizations and the local government authorities of the County of London. I can personally testify to the enormous amount of time, diplomacy, and tact which he whole-heartedly devoted to this task, the immense sacrifice which he must have made in his own private professional life, the wise counsel and statesmanlike attitude which he adopted all through this period, filled as it was with many difficulties and much controversy. But it is pleasing to be able to record that far more than any other individual member of our profession he did succeed to a very considerable extent in bringing about a large measure of valuable co-operation between voluntary organizations and public authorities, of which a striking example was the British Postgraduate Medical School at Hammersmith Hospital.

To me one of the most remarkable features of Dawson's extraordinarily busy life was the fact that I never remember him being in a hurry at any time from early morning up to late at night. He possessed in full that marvellous gift of making you feel that when you were in his presence for any purpose you were the only person in the world at that moment in whom he was interested and that you had all the rest of his day at your disposal if you wanted it. Add to this priceless gift the fact that he had an exceptionally charming personality, a delightful sense of humour, a heart of gold, a vast fund of common sense and worldly wisdom, a statesmanlike attitude towards problems of national importance, and it becomes easy to understand how and why he rose to greater heights than were ever previously attained by any member of our profession in the social, political, and scientific world. No doubt many of his friends will bear their testimony to his professional abilities and achievements, but may I add a purely personal experience of him as the "beloved physician." In the spring and summer months of 1934 I was confined to bed by a long and wearisome illness, during which Dawson came to see me at frequent intervals. Ultimately he advised me to go to a seaside nursing home at Hayling Island. A few weeks later I received about midday a telephone message from his London residence to the effect that he was coming to see me about 5 p.m. He arrived and spent some time in thoroughly overhauling me, followed by a very encouraging prognosis. Then he sat down by my bedside and we talked about many subjects of mutual interest. At 7 p.m. he said, "Well, now I must leave you." I said I supposed he was going to spend the night with a relative of his whom I knew was at that time living in the neighbourhood of Hayling Island. He replied: "Oh, no; I am only on my way to Scotland for a holiday, and to-night I shall motor as far as Cheltenham, and to-morrow from there to Ruthin Castle, and then on to Balmoral." That incident was characteristic of Dawson's wonderful kindness and thoughtfulness. He had deliberately travelled hundreds of miles out of his way to see and to cheer up a sick friend. I have no doubt that, if space permitted, many hundreds of his friends and colleagues could give similar examples, and in every case without the remotest idea on Dawson's part of either fee or reward. It is therefore not to be wondered at that to so many of us he was Bertie Dawson, the wise as well as the beloved physician.

Dr. ALFRED COX writes:

May I be allowed to add a postscript to your grateful tributes to Lord Dawson? It was during the Centenary Meeting of the Association that I saw most of him, and I vividly remember the grace with which he presided over the many functions which fell to his lot at that time, and the ungrudging way in which for two years he gave time and thought to every detail. The two strongest impressions of him left on my mind were the way in which he kept his mind, as well as his body, young; and the fact that all his honours had left him completely unspoiled. It was always a pleasure to deal with him.

Your reference to Lady Dawson would have pleased him, for during our Centenary programme it was charming to see how implicitly he relied on her help and how she infused into everything she did—and it was much—that grace and charm which seem to have been Nature's gift to the partnership. The affectionate sympathy of everybody who had the honour of working with her husband goes out to her at this time, and we hope it may help her.

HAROLD FARLEY SEYMOUR, M.D.Lond., F.R.C.S.Ed., F.R.C.O.G., who died on March 6 at Rottingdean, was born in 1879 in Plymouth, and was educated at Plymouth College, and afterwards at the London Hospital. He qualified M.B.Lond. in 1901, and after holding various resident appointments at the West London Hospital he settled in general practice in Worcester City. He soon took a special interest in obstetrics, and obtained the M.D.Lond. in Obstetric Medicine in 1906. During the last war he served in the Royal Navy, and after release he settled in Brighton, took the F.R.C.S.Ed. in 1920, and then moving to Hove he specialized in obstetrics and gynaecology. In this specialty he quickly established a county reputation. He was made a foundation member of the Royal College of Obstetricians and Gynaecologists, and in 1937 the Fellowship was conferred upon him. He held many appointments, including that of honorary surgeon to the Sussex Maternity and Women's Hospital and honorary gynaecological surgeon to the Hove Hospital. Harold Seymour was a most industrious, conscientious, and proficient worker. Throughout life he was dogged by ill-health, with which he battled with unflinching courage. He was greatly admired by all his patients, for whose benefit he never spared himself, and he was esteemed and respected by his colleagues. Apart from his chosen work, which came first, his only other interest was mountain climbing. He was a member of the Alpine Club and the Swiss Alpine Club. He was a charming and courteous host, and will be greatly missed by a large circle of friends and patients.

Medical Notes in Parliament

PAPER FOR BOOKS

In the House of Lords on March 14 Lord ELTON called attention to the excessive restrictions on the supply of paper for book publication and moved for Papers. He said the facts were that up to the end of last October every publishing house which had been in existence before the war was entitled to an allotment of 40% of its pre-war consumption of paper. That meant in the aggregate 20,800 tons. There was also a small quantity of 1,700 tons which was distributed by the Board of Trade on the advice of a committee of publishers sitting under the chairmanship of Sir Walter Moberly. That brought the grand total up to 24,400 tons. There was a total distribution to all users for all purposes of 447,000 tons, of which 100,000 tons went to the Stationery Office and 50,000 to the War Office. Then last October there was an increase from 40% to 42½%—an increase of 1,300 tons, together with an increase of 600 tons in the Moberly pool—1,900 tons in all. Despite a recent deputation from Members of Parliament, the only later increase in the allotment had been one of an additional 1,000 tons for this Moberly pool, which was a selective pool, through which extra tonnage was given to applicants on merit.

No one expected that book production should flourish in war as in peace, but thus excessively pruned, under severe restrictions, books could not possibly play their part in the war effort. Liberated Europe needed British books to fill a five-years gap in their own libraries. They needed them to discover how the British lived and thought during these five years, and they needed them to take the place of Germany as the primary source of textbooks for the Continent. At home there was a desperate need for educational books for training the additional teachers required under the new Education Act, and for pupils as a result of the raising of the school-leaving age; books would soon be needed, too, for the returning university students. They were needed for the general public and for the Services. For the ordinary book allotment 10,000 more tons of paper a year were wanted.

The EARL OF HUNTINGDON asked whether it would not be possible (1) to give a higher priority to and allow a larger percentage of paper for books; (2) to release gradually from the Forces men and women who were either experienced printers or bookbinders or who had had experience of work in publishing houses; (3) to give some priority to the replacement of book-making machines which had got out of order; and (4) to import more pulp or more means of making paper as soon as the shipping situation allowed. He understood that a grass that had been discovered in New Guinea made extremely good paper.

Viscount MERSEY, speaking for Lord Samuel, said that the Red Cross had asked for about 500 books from educational libraries; 30% were reported as "not available," 30% were entirely unobtainable, and the balance were obtainable in very small quantities. Lord LANG said that the root of the difficulty was failure to regard the supply of books as a matter of very real, practical, national importance.

The EARL OF JERSEY supported the motion, but said he was astonished at the moderation of Lord Elton's demand for 10,000 tons. He would put it at three times that amount.

MEDICAL TEXTBOOKS AND JOURNALS

Viscount BUCKMASTER raised the question of the supply of paper for medical publications. He said that medical publications, in which he included journals and periodicals, were so restricted that it was difficult to see how the study of medicine could be pursued or how medicine could be practised in the manner expected. Publishers were now quite unable to supply the basic minimum of books needed by medical students. No one would dispute that anatomy was an essential part of the medical knowledge of a doctor. He could not imagine anyone being anxious to undergo an operation by a surgeon who had not a fairly full knowledge of it. The leading work, *Gray's Anatomy*, was quite unobtainable. He had tried to get it, either new or second-hand, without success. The same applied to *Buchanan's Anatomy* and *Cunningham's Anatomy*. In physiology, matters, if anything, were worse. In one class 15% of the students could not beg, borrow, or by any means short of theft obtain a copy of any of the leading works. How could men pursue their studies under such conditions? These facts about students' books were shocking, but there was also the medical man in practice, who would find it hard indeed to keep abreast of modern medical knowledge. It was not merely that writers were prevented by the shortage of paper from writing books, but there was a shortage of journals and periodicals. The latter were the arteries through which medical knowledge and information circulated. Yet here was an alarming position. The editor of one of these journals advised him that he had a waiting list of 1,500 doctors seeking to become subscribers and to obtain copies; also that he was quite unable to meet the demands for his journal from the liberated countries. This was unfortunate. The editor of another assured him that he could not in any way meet the demands of his subscribers, that his correspondents were drastically cut down, and that much medical knowledge of the first importance could not be passed on. It was not only the medical man in practice who needed these journals; they were essential to the medical research worker. He must have the power to express his findings as and when he pleased. He must keep in touch with the progress of his fellow workers in this country and abroad, especially in the United States. A Fellow of the Royal Society had told him that his colleagues in research did not expect to have a single paper published until 1946. How could they continue their work in such conditions? What sort of encouragement was that to give them? If the advance of medical knowledge was retarded the community as a whole was penalized.

A good example was provided in the field of social medicine. The Goodenough Committee had urged that this should receive every possible encouragement. Many young men and women were seeking to work in this sphere. Here was something which one would think would appeal to the Government, who would at least be anxious to encourage it, but the Ministry of Supply had refused the B.M.A. one ton of paper a year for starting a *Journal of Social Medicine*, a journal in which workers in this field might enjoy that free expression of opinion so essential to their work. These restrictions were not only disheartening to medical men, they were damaging to the public also, and at a time when ever greater demands were being made on medicine. The number of doctors had greatly increased—it was something like 12% more than in 1938. Even with these figures it was clear that the total demands of paper for the medical world were negligible compared with the amount in daily use. Even if all restrictions were now removed it would be a long time before supplies could catch up with demand, and he urged the Minister, to whom he had written personally on this matter, to do his utmost to see whether some additional grant could be made before we lost ground which could never be regained.

The **EARL OF SELBORNE**, Minister of Economic Warfare, who replied, said that the Government was aware of the immense importance of books, especially at this time. But although we had more ships to-day than ever before, shipping shortage was greater than ever owing to other demands. Lord Elton had asked for 10,000 tons of paper; Lord Jersey had said that 30,000 tons was needed. He had been advised that the paper would not at the moment be procurable in America; we had in fact acquired all the paper that we could in America, so that an additional 30,000 tons, or even 10,000 tons, was not possible. Moreover, every ton of shipping just now was required for pursuing the war and for feeding the liberated peoples of Europe. Paper was not the only bottle-neck in the matter; labour in the printing and publishing trades was also in very short supply. We were faced with a shortage of paper in America, with the biggest shortage of shipping that we had yet experienced, and with the greatest shortage of man-power in all trades. On the top of that was a very greatly increased demand for books.

The Government had tried to divide the paper supplies equitably. A bigger allocation for books could only be obtained either by importing more paper and releasing more man-power, which was not possible at present, or else by making cuts in the allocations to other industries. It was not the book publishers who had had to submit to the biggest cuts. They were now receiving something like 42% of their pre-war requirements; newspapers, on the other hand, receive only 25%.

As regards medical books, about which Lord Buckmaster had spoken very strongly, he was advised that partly as a result of the efforts of the committee presided over by Sir Walter Moberly the publication of medical books at this moment amounted to 80% of what it was before control. But if there were the deficiencies Lord Buckmaster had mentioned then this was a matter which required the most serious consideration from the authorities concerned, and he would draw the attention of the President of the Board of Trade to the remarks made on that question.

Lord **ELTON** withdrew his motion.

What is Immunity?

Mr. **ALFRED EDWARDS** inquired on March 6 whether the Army Medical Department used the word "immunity" to mean "protected from a disease"; or what was the meaning of the word in reference to vaccination and the various inoculations. Sir **JAMES GRIGG** said the term "immunity" was used by the Army Medical Department to describe the effects of protective treatment against certain diseases. There were degrees of immunity, which necessarily varied in accordance with certain factors—for example, the resistance of the patient to a particular parasite.

Recruitment of Doctors

Sir E. **GRAHAM-LITTLE** inquired on March 8 whether the Minister of Health had considered an example submitted to him of the dissatisfaction among senior medical officers serving abroad at the small proportion of newly qualified medical practitioners called up for military service abroad in exchange for senior officers and the large number drafted into the E.M.S. at home. Mr. **WILLINK** said he had considered a letter which Sir Ernest had forwarded, but pointed out that the great majority of newly qualified medical practitioners fit for military service were already being called up after short periods in resident hospital appointments, which were necessary to provide the experience required for subsequent military service. Resident hospital posts were limited in number to the minimum wartime establishments approved for each hospital by the Central Medical War Committee. It was the policy of that committee wherever possible to call up the holders of the senior posts after a certain period so that a proper flow of young practitioners through these posts to the Forces could be maintained.

Notes in Brief

The process is continuing of release by the Service Departments of members of the Women's Auxiliary Services with nursing experience, including mental nurses, who desire to return to civilian nursing.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Sir Lionel Ernest Howard Whitby, M.D., has been elected a Honorary Fellow of Downing College.

The Raymond Horton-Smith prize has been awarded to F. T. C Prunty for his M.D. thesis on "Hyperfunction of the Adrena Cortex."

The Council of the Senate gives notice of an election to Imperia Chemical Industries Fellowships in the Easter Term, with tenur from Oct. 1, 1945. The beginning of tenure may be deferred for candidate engaged on national service, or on other work of nationa importance, until he is released from that work. The Fellowship have been established for original research in Physics, Chemistr Engineering, Metallurgy, Pharmacology, Chemotherapy, or in subject related to one or more of these branches of science. Fellow will ordinarily be required to carry out their research in Cambridg and part of their duties will be to undertake university teaching o the recommendation of the Head of the Department in which th Fellow is working. Persons of either sex may be elected. A Fello who on election is not a member of the University or of Girton o Newnham College will be admitted, if a man, as a member of th University, or, if a woman, as a member of Girton or Newnha College. Fellowships will be tenable for periods to be determine in each case by the managers, but not exceeding five years in al The annual stipend will normally be £600, but may be varied; will be subject to deduction of 5% under the University Supe annuation Scheme. A Fellowship will not be tenable with stipendiary Fellowship of a College, or with any University studen ship or scholarship, or with any University office. Applications mus reach the Registrary, at the University Registry, not later tha April 30. They should contain particulars of the subject in whic the candidate proposes to research, and must be accompanied by statement of his career (including date of birth), by copies of an papers he may have published, or by references thereto, and by th names of at least two referees. Not more than two testimonia may be sent. The Universities at which Imperial Chemical Industrie Fellowships are tenable are Birmingham, Cambridge, Durham, Edi burgh, Glasgow, Liverpool, London, Manchester, and Oxford. Fo conditions of candidature at Universities other than Cambridge th notices issued by those Universities should be consulted.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

Dr. Macdonald Critchley, F.R.C.P., will deliver the Croonian Le tures on "Problems of Naval Warfare under Climatic Extremes before the Royal College of Physicians of London (Pall Mall Eas S.W.) on Tuesday and Thursday, May 8 and 10, at 4.30 p.m.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

RESTORATION FUND

The King has honoured the Royal College of Surgeons of Englan by making a donation to the Fund for the Restoration and Develo ment of the College, which suffered serious damage by enemy actio in 1941. His Majesty is Visitor of the College, and the Preside and Council and all Fellows and Members are extremely gratef for this further mark of His Majesty's favour and for the consta encouragement the King has given to them in the heavy task whic lies before them.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the incidence of infectious disease declined, there being 736 fewer notifications of measles, 21 of acute pneumonia, 83 of scarlet fever, and 77 of whooping cough.

Except that Yorks West Riding reported 41 fewer case than last week, the local trends of scarlet fever changed littl Whooping-cough was less prevalent in the north; in the sout there was a small rise. The notifications of measles continue to mount in the south; the combined areas of London an the south-eastern and south-western counties had an increas of 524. Leicester had 203 more cases than last week, an Nottinghamshire 147; but Derbyshire had 257 fewer, Lanca shire 190, Cheshire 181, Warwickshire 180, Durham 15 Middlesex 146, Staffordshire 141, Essex 129, and Yorks Eas Riding 115.

The incidence of dysentery continues high. There wer fresh outbreaks during the week in Buckinghamshire (Ame sham R.D. 13, Eton R.D. 20), Dorsetshire (18; Sherborne U.D 13), Southampton (16; Bournemouth C.B. 5; Andover M.B. 11)

Notifications in London rose from 34 to 69; of these, 31 were reported in Stoke Newington, and the remaining 38 involved seventeen boroughs. Other large returns were Lancashire 29, Yorks West Riding 27, Essex 27, Middlesex 18, Surrey 17, Gloucestershire 15, Devonshire 14, Cheshire 13.

In *Scotland* 29 fewer cases of scarlet fever were reported, and 20 of measles. Notifications of dysentery rose by 30, the incidence of this disease having increased by 100% since January. The largest returns of dysentery were in Edinburgh 35, Glasgow 35, Falkirk 23, Renfrew County 19. There has been a widespread attack of violent sickness and mild dysentery in Southern Scotland. The illness lasts two or three days, but leaves the patient weak and unfit for work for another week. The cause of the outbreak has not been discovered.

In *Eire* there were 8 more cases of diphtheria than last week, but the notifications of measles were halved.

In *Northern Ireland* diphtheria notifications fell from 25 to 7, and measles from 93 to 87.

Influenza

If judged by the number of deaths from this cause in the great towns the seasonal rise of influenza mortality during this winter has been unusually light and of very short duration. Taking for comparative purposes the period when the weekly deaths were 50 or more as the peak of the epidemic curve, the following distribution is obtained for the great towns.—

	1944–5	1943–4	1942–3	1941–2	1940–1	1939–40	1938–9
No. of consecutive weeks when deaths were 50 or more	8	13	14	11	16	16	19
No. of deaths in these weeks	532	5,435	1,211	791	2,391	4,798	3,376
Average number of deaths per week	67	418	87	72	149	300	178

Quarterly Returns for Scotland

The birth rate during the December quarter was 18.8 per 1,000, the highest rate for a fourth quarter since 1930. Infant mortality was 64 per 1,000 registered live births, this being 8 below the average of the five preceding fourth quarters. Maternal mortality was 3.0 per 1,000 live births; this rate is considerably lower than that of any previous December quarter and almost the lowest for any quarter in Scotland. The general death rate of 13.1 per 1,000 was the same as the five-years average. The death rates from all forms of tuberculosis and from respiratory tuberculosis were 72 and 58 per 100,000, and were respectively 1 and 3 above the five-years average. There were 46 deaths from diphtheria, 42 from whooping-cough, 7 from measles, and 6 from scarlet fever.

The preliminary return for the whole of 1944 shows that the birth rate was 19.2 per 1,000, and was the highest rate recorded for Scotland since 1930. Infant mortality, at 65 per 1,000 live births, was the same as in 1943, the lowest rate recorded in Scotland and 12 below the pre-war average (1934–8). The general death rate was 12.9 per 1,000, and 0.7 below the average of the five preceding years. 183 deaths—the smallest number ever registered from this disease—were attributed to diphtheria. Deaths from other infectious diseases were: whooping-cough 179, cerebrospinal fever 94, measles 46, scarlet fever 9, typhoid and paratyphoid fevers 6. Deaths from all forms of tuberculosis and respiratory tuberculosis numbered 3,935 and 2,978 respectively, compared with 3,959 and 2,976 in 1943.

Week Ending March 10

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,424, whooping-cough 1,502, diphtheria 472, measles 25,049, acute pneumonia 813, cerebrospinal fever 77, dysentery 412, paratyphoid 5, typhoid 5.

The second series of postgraduate scholarships for nurses (the first were given last year), which are being awarded by the Hospital Saving Association out of its 21st birthday funds, include two scholarships for nursing administrators of approximately £250 each; two for nurse dietitians of £250 each; four for nurse teachers of £250 each; four for health visitors of £105 each; six for industrial nurses of £65 each; and four for midwife teachers of £75 each. In future years the H.S.A. may vary the scholarships in number or in kind. As last year, the scholarships will be available at any of the recognized training centres, and are open to nurses who are registered in the general part of the State register and have trained in a voluntary or local authority hospital within the area of King Edward's Hospital Fund for London. Candidates will be required to sit for a competitive examination conducted by the Royal College of Nursing, from whom, at 1A, Henrietta Place, Cavendish Square, W.1, application forms and all particulars may be obtained.

No. 9

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 3.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)				
	(a)	(b)	(c)	(d)	(e)	(a)	(b)	(c)	(d)	(e)

Annual rate per 1,000 persons living			16·4	21·4	§			17·6	31·7	§
Stillbirths	213	28	33			244	33	38		
Rate per 1,000 total births (including stillborn)			39					42		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

Celebrations in connexion with Lawson Tait's Centenary will be held in Birmingham at the end of next June. The Midland Medical Society, the Women's Hospital, and the University are sponsoring the arrangements. It is probable that these will consist of an oration in Tait's honour and other functions as circumstances permit.

A meeting of the Medical Society for the Study of Venereal Diseases will be held at 11, Chandos Street, W., to-day (Saturday, March 24) at 2.30 p.m., when a communication on "Early Syphilitic Infection treated by Intensive Arsenotherapy and by Penicillin" will be given by Surg. Capt. T. R. Lloyd-Jones, R.N., and Surg. Lieut.-Cmdr. F. G. Maitland, R.N.V.R.

A meeting of the Middlesex County Medical Society will be held at West Middlesex County Hospital, Isleworth, on Tuesday, March 27, at 5.30 p.m., when Sir Joseph Barcroft, F.R.S., will speak on "Movements of the Human Foetus," illustrated by a film produced by Dr. Deane, Miss Titcombe, and members of the obstetric staff. At 6.15 p.m. Mr. Frank Law will talk on "Ophthalmoscopy in General Medicine."

Dr. Robert Sutherland will give an address on "The Principles and Methods of Health Education" before a meeting of the Polish Medical Association in the United Kingdom at B.M.A. House on Tuesday, March 27, at 5 p.m.. A discussion will follow. All interested persons will be welcome.

A meeting of the Paddington Medical Society will be held at St. Mary's Hospital, W., on Tuesday, March 27, at 9 p.m., when Mr. F. A. Juler will give a lecture on "Modern Remedial Measures in Ophthalmology."

A meeting of the Scottish Group of the Association of Industrial Medical Officers will be held in the orthopaedic department of the Western Infirmary, Glasgow, on Wednesday, March 28, at 2.30 p.m., when papers will be read by Prof. C. W. Illingworth on "The Peptic Ulcer, with Special Reference to Factory Conditions," and by Mr. Roland Barnes on "Treatment of the Painful Shoulder, and the Problem of Resettling in Industry." Clinical cases will be demonstrated. Medical practitioners interested in industrial medicine are invited to attend.

The Royal Society has now been informed that H.M. Treasury has made provision in the estimates for the fiscal year 1945-6 for the following grants which are administered by the Royal Society: for scientific investigations, £14,000; for scientific publication, £7,000; for scientific congresses, £1,600. In view of the greater amounts to be available if these estimates are accepted by Parliament, and of present changing conditions, the Royal Society has decided that more frequent allocation is desirable. The last dates, therefore, in 1945, for receiving applications for grants from the Parliamentary grant-in-aid for scientific investigations will be March 31, July 31, and Nov. 30, and the last dates for receiving applications for grants from the Parliamentary grant-in-aid for scientific publication will be June 15 and Nov. 15.

According to a joint statement by the Ministries of Supply and Health production of penicillin is now increasing rapidly and distribution is being expanded. Supplies will shortly be sent by the Ministry of Health to more than 200 large hospitals, which will issue it to smaller hospitals as required. Most of the cases treated with penicillin will be in hospitals, but general practitioners will be able to get supplies for patients who cannot be taken to hospital. It is too early yet to say when distribution will start through ordinary commercial channels.

As a result of severe damage to the in-patient department of the West End Hospital for Nervous Diseases, London, it has been necessary to abandon the buildings for the present. Temporary in-patient accommodation at the Princess Louise Hospital for Children, North Kensington, has been obtained by the courtesy of the committee of management. The out-patient department of the hospital continues as usual (with daily clinics excepting Saturday) at Welbeck Street, W.1.

A portrait by Mr. Frank Salisbury of the late Mr. L. R. Braithwaite, the distinguished Leeds surgeon, was unveiled in the board room of the General Infirmary at Leeds on March 2 by Mrs. Braithwaite, after it had been presented by Mr. Digby Chamberlain, on behalf of the subscribers, to the chairman of the Board of Management. A replica has been accepted by the Royal College of Surgeons of England, of which at the time of his death Mr. Braithwaite was a vice-president.

Sir Robert Hutchison has been appointed consulting physician to the Royal Dental Hospital of London in succession to the late Sir Humphry Rolleston.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, British Medical Journal, B.M.A. House, Tavistock Square London, W.C.1. Telephone: EUSTON 2111. Telegrams: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded fo publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs Authors over-seas should indicate on MSS. if reprints are required, as proof are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.) Telephone: EUSTON 2111. Telegrams: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. Telephone: EUSTON 2111. Telegrams: *Medisecra Westcent London.*

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Pregnancy and Acute Rheumatism

Q.—*A woman of 25 had acute rheumatism at the ages of 10 and 17 Since then she has enjoyed good health and was able to complete her training as a nurse. On routine medical examination a diagnosis was made of mitral stenosis, but she was accepted for military service. She now wishes to know if it would be safe for her to have a baby. Examination reveals no evidence of heart disease except a systolic murmur. Since the second attack she has restricted her activities—no cycling, no swimming, no hill-climbing. What advice should be given?*

A.—In assessing the prognosis for pregnancy in a patient who has had rheumatic fever it is important to know what effect, if any, the disease has had on cardiac function. Three main facts must be taken into consideration: the nature of the cardiac lesion, the degree of cardiac enlargement, and the exercise tolerance. In this case precise data on these three points are not given. It is stated that a diagnosis of mitral stenosis was made, although there is apparently only a systolic murmur and no diastolic murmur. Possibly the diastolic murmur can be elicited only after exercise. The degree of cardiac enlargement is not stated, nor is there evidence of the present state of the patient's exercise tolerance, since only voluntary restriction of activity is noted. But as she has been able to carry out her training as a nurse successfully, it seems that her exercise tolerance is not seriously impaired. If *exercise tolerance is good and there is no cardiac enlargement*, this patient could reasonably be expected to go through two or even three pregnancies without any risk of deterioration in the cardiac condition. Careful supervision would be essential. If a serious breakdown of cardiac function should occur during pregnancy, the patient should be advised not to become pregnant again. In any case, pregnancies should be spaced so as to ensure an interval of two to three years between each child. The chief danger in this case would lie in a fresh attack of rheumatic fever, especially if this occurred while the patient was pregnant. The chance of this is slight.

Thallium Acetate, Hirsutism, and Baldness

Q.—*Can you tell me if thallium acetate can be used for hirsuties other than by internal consumption?*

A.—Over 30 years ago Dr. Sabouraud of Paris was consulted by a number of patients suffering from baldness. All of them had been victims of an epidemic of enteritis, prevalent at that time in Paris Sabouraud, with his acute mind, discovered that the baldness occurred only among patients who had been given acetate of thallium by the mouth in the treatment of the epidemic, and that led him to use acetate of thallium in an ointment for superfluous hairs. The practice has been entirely abandoned because it has been found that acetate of thallium acts only if absorbed in amounts sufficient to cause fall of hair—a dose that is always dangerous in an adult. The answer to the question is that treatment of this kind is either valueless or dangerous.

Raynaud's Disease

Q.—*A woman aged 45 has Raynaud's disease. The first and second fingers of each hand have some small black patches of gangrene on them. There is no albumin or sugar in the urine, and the blood pressure is normal. Any suggestions for treatment, apar from operation, would be welcome.*

A.—Gangrene of the fingers in Raynaud's disease is nearly always associated with thrombosis of the digital arteries; recovery, with the recanalization of these arteries and the opening up of smal collaterals. The blood-flow to the affected digits can be increased to the limit which the vessels will carry by a cervico-dorsa sympathectomy, or alternatively by keeping the body warm. The crease in blood-flow produced by warming the body adequately is t least as great as after sympathectomy. The only difficulty is to aintain an adequate degree of heat. If the patient is in bed, four six hot-water bottles arranged near the trunk, and changed every to 6 hours, usually suffice. If the patient is up, a warm atmosphere and thick clothing to the body are the best methods.

Ethyl Alcohol and Shortage of Spirits

Q.—*It is impossible to obtain spirits for use as a stimulant in the ards, and the Government has prohibited the manufacture of sal olatile; so I have recently given patients diluted ethyl alcohol, oloured and flavoured, as a substitute. Is there any medical objecion to ethyl alcohol being given in place of brandy or whisky?*

A.—There is no objection on medical grounds to the use of suitbly flavoured and diluted ethyl alcohol. It can act as a stimulant nly by reflex from local irritation. After absorption it is purely epressant.

There is a strong reason why alcohol should not be used in this anner, and that is that there is a shortage of it. We have been sked to avoid prescribing tinctures on that account.

Post-operative Venous Thrombosis

Q.—*Is a patient with recent post-operative thrombosis of the deep emoral veins liable to embolism if allowed to walk or move unduly? he routine for patients who develop unilateral oedema of leg during he post-operative period is immobilization; how long should this e maintained?*

A.—Direct evidence of the kind here asked for is difficult or mpossible to obtain, but certain conclusions may be drawn from ndirect evidence. In 1941 N. W. Barker and other workers at he Mayo Clinic investigated 1,260 cases of venous thrombosis after peration; among these there were 273 cases of clinically diagnosed lio-femoral thrombosis, of which only 18 were followed by fatal ulmonary embolism. The embolus commonly came from a recent hrombus in the apparently unaffected limb; when it came from the wollen limb it was always within the first four days of the clinical ymptoms. They conclude: "After thrombo-phlebitis has developed nd existed for more than three or four days the thrombus does not etach to form an embolus, but emboli may occur if a new thrombus orms in a proximal vein or in a vein elsewhere in the body" (*Proc. Mayo Clin.*, Jan. 15, 1941, p. 33). From this we may infer that ovement of the affected limb is not likely to lead to detachment f the primary thrombus after the fourth day. The chief aim should e to prevent thrombosis in other veins by the use of heparin or llied drugs. When a patient develops oedema of one leg after peration, it is usual to immobilize the limb for a period of from to 6 weeks.

Enlarged Prostate and Defaecation

Q.—*A man aged 68 has a moderately enlarged, non-malignant rostate, without much urinary frequency. His chief trouble is the ccasional tendency to defaecate when he is about to micturate.*

A.—Difficulty in micturition due to prostatic obstruction is always liable to cause a patient to feel that he may defaecate at the same ime as he is emptying his bladder. There is no remedy for this xcept either to deal with the obstruction or to ensure that the lower bowel is empty.

Certification of Lunatics

Q.—*What is the legal process, now, as to certification of lunatics? I am told that I cannot alone certify anyone, but must call in the elieving officer, even for a "three-day order."*

A.—The ordinary procedure of certification in lunacy requires two medical certificates, which are issued by two independent practitioners in support of a petition presented by the nearest relative of the patient to a judicial authority, who signs a reception order authorizing the patient to be received and detained. There are, however, circumstances in which a patient can be lawfully detained on one medical certificate. If a patient is likely to injure himself or others unless he is restrained at once, he may be received into care on an urgency order. This is signed by the nearest relative available and supported by one medical certificate, which need not be given by the usual medical attendant. The patient must be received within two clear days, and the order remains in force for seven days only. Such an order may be used for the reception of a rate-aided patient, but then it must be signed by the public assistance officer. Similarly, a summary reception order made by a justice of the peace for the reception of a rate-aided patient is supported by one medical certificate. This kind of order may also be used for a person of unsound mind not rate-aided who is wandering at large, or not under proper care and control, or cruelly treated or neglected.

The expression "three-day order" does not seem to correspond to any order recognized by the Lunacy and Mental Treatment Acts; and it is not legally necessary in the circumstances outlined above for the certifying practitioner to associate himself with the relieving officer unless an urgency order is used for the reception of a rate-aided patient.

Urea and Migraine

Q.—*What is the rationale of treating cases of migraine with urea? Has any work been published to show in what proportion of cases this is successful, or which type of case is benefited? How long should the treatment be continued?*

A.—An association between water retention and attacks of migraine is frequently observed, an oliguria making its appearance immediately before or coincidently with an attack. In some patients the water retention may be explicable, though in a somewhat speculative way, by dietetic, endocrine, or neurological hypotheses. A high carbohydrate intake is often associated with water retention, especially in women, and cases of migraine associated with such a diet have often been reported (e.g., Hare, *The Food Factor in Disease*, London, 1905). In many women a water retention of endocrine origin occurs immediately before the menstrual period, a time at which some patients are liable to severe headache. The headache is relieved coincidently with a profuse diuresis when menstruation is well under way. I have seen a patient in whom there was clinical evidence of a functional derangement of the hypothalamus (obesity, sexual weakness, disturbance of the sleep rhythm, excessive sweating, hyperpiesis) and in whom migraine and extreme oliguria (amounting almost to anuria) alternated with diuresis and freedom from attacks. He was permanently relieved by diet and diuretics. J. A. Brown (*B.M.J.*, 1943, **2**, 201) reported the case of a man whose migraine was accidentally relieved during a urea-concentration test, both he and Sir Walter Langdon-Brown (*B.M.J.*, 1943, **2**, 430) referring to the findings of Goldzieher that in migraine there may be severe water retention. A full bibliography can hardly be given in a short reply, but the evidence that in *some* cases there is a relation between migraine and water retention is strong though by no means complete. It is quite certain that many patients do not fall into this group at all. Treatment by means of a low-carbohydrate, low-fat, low-fluid, low-salt, high-protein diet combined with diuretics (e.g., urea 15 grammes t.d.s.) is worth trying in every case. It certainly works in some. The treatment can often be "slackened off" gradually, but to some extent it must be continued permanently.

"Grumbling Appendix"

Q.—*What is the mechanism which produces a "cure" in a moderately severe case of gastroptosis where a grumbling appendix is removed. The patient had considerable mental anxiety prior to the gastroptotic condition, and the writer can recollect being informed by an eminent London surgeon that a grumbling appendix does not exist.*

A.—It is extremely doubtful whether such a pathological condition as chronic appendicitis exists, though recurrent appendicitis and peri-appendicular adhesions following an acute attack of appendicitis might be included under the heading of a "grumbling appendix." Abdominal pain and distress due to enterospasm may occur as symptoms of an anxiety neurosis, particularly in the asthenic visceroptotic type of patient. Many factors contribute to the relief produced by operation: on the superficial level, confinement to bed, withdrawal from a distracting environment, sympathy, etc.; on the deeper level, symbolic removal of the bad internal object which is responsible for the anxiety, self-punishment, etc. The policy is merely one of appeasement of the neurosis, the "cure" is likely to be short-lived, and other symptoms of the neurosis are likely to become increasingly troublesome.

Application of Unna's Paste Bandage

Q.—*A patient who must be up and about finds elastoplast unsuitable for his varicose ulcer of the leg. What treatment do you suggest?*

A.—The best treatment for this patient is the small but important operation of simultaneous ligature and injection of the varicose veins. It will cause incapacitation for a week. Failing this, an Unna's paste bandage is the best remedy. The ulcer and leg are cleaned with methylated ether: the "sulpha" drugs should be avoided, because some patients prove to be hypersensitive to them with a closed bandage, and develop an intractable dermatitis.

The application of the Unna's paste bandage is important. First, the leg should be elevated for at least half an hour and a firm cotton bandage applied with a view to reducing the swelling. The preparation of the Unna's paste bandage is as follows: An ordinary three-inch cotton bandage is loosely re-rolled, at the same time clearing the edges freely of the cotton shreds. It usually needs two, possibly three, bandages for one leg. These are autoclaved and then dropped into a jar of boiling Unna's paste for a quarter of an hour. The bandages are lifted out into a sterile receiver until they are cool: they are therefore sterile. Longitudinal strips of three thicknesses of bandage are placed over the front, sides, and back of the leg: these are to prevent the transverse turns of the bandage cutting into the skin, and are essential if the application is to be comfortable and retained—as frequently they are—for 6 to 12 months. The bandage begins at the root of the toes with the foot in a comfortable dorsiflexed position: this also is necessary to minimize the transverse creases which are the cause of discomfort to the wearer. The bandage is applied with a moderate amount of tension, special care being taken that it is free from creases, twists, and folds. It takes several minutes to apply, but when it is recalled that the correct application will heal the ulcer and will stay on for months, it is worth the trouble. Each turn of the bandage overlaps its predecessor by two-thirds, so that the final Unna's paste casing is three thicknesses plus the three thicknesses of longitudinal strips. These dressings are always well tolerated; it is the exception to find a patient whom they do not suit. Finally, the wet bandage is dried off by the application of an ordinary cotton bandage beginning at the knee and passing downwards; the bandage will be found to lie better when so applied. Plaster-of-Paris is useless for encouraging epithelization, and, moreover, is unnecessarily inconvenient.

Patients with ulcers must wear stout shoes from early morning to last thing at night; ladies should be advised to procure a boy's shoes, which are made in wider fittings and are robuster than ladies' shoes. The local cobbler will raise and smarten up the heels.

Recurrent Polyneuritis

Q.—*A woman of 72 has had three attacks of severe polyneuritis in the past 10 years. Each attack lasted 2 to 3 months, with symptoms, except for slight numbness, subsiding completely between the attacks. She has had a myocarditis and complete achlorhydria for some 15 years. What are the aetiology, treatment, prevention, and prognosis? Should vitamin B be taken regularly either by mouth or by injection, and if so, in what dosage?*

A.—Recurrent polyneuritis is a rare disorder, the cause of which is not known. There is evidence that in some cases avitaminosis may be one factor in its aetiology, and in the case reported the complete achlorhydria is perhaps more consistent with a metabolic than an infective cause. If the laboratory facilities are available, something might be learned by measuring the patient's urinary excretion of vitamin B_1. For prophylaxis the patient should take all the vitamins of the B group. Tablets providing 1 mg. each of vitamins B_1 and B_2 and 15 mg. of nicotinic acid amide are on the market, and one of these three times a day would give an adequate dosage, assuming absorption from the alimentary canal to be normal. It would also be wise to give an intramuscular injection of liver extract in doses of 2 to 4 c.cm. once a month. If another attack of polyneuritis occurs the same treatment should be continued with the addition of a daily injection of 10 mg. of vitamin B_1, and the physical treatment appropriate to polyneuritis. The prognosis is uncertain and further attacks may occur.

Nose-picking and Nail-biting

Q.—*A boy of 7 years (adopted at 6 weeks old, and brought up knowing this fact) has been biting his nails and picking his nose for about a year. He is getting worse. What should be done?*

A.—Judging from the facts given, this case appears to be one of mixed aetiology. The constitutional factors should first be investigated, especially the calcium metabolism; for parathyroid deficiency often gives rise to such tics. Psychologically, the Freudians regard nail-biting and nose-picking as sexual manifestations related to masturbation, and this view is often borne out by the facts. But, taken in itself, nail-biting reveals a state of tension, and is evidence of repressed assertiveness or aggression. (Children suffering from pent-up energy, say before an examination, often bite their nails.) The thwarting may be caused by undue external discipline, but it may also be the result of conditions in the child's own mind; these latter require special investigation by a child psychiatrist. The thwarting may, in fact, be due to the feeling of inadequacy caused by the physiological deficiency already referred to. As a first-aid measure, the child should be encouraged to do things with his hands, both in order to employ his hands and also to give outlet to his assertiveness and to give him confidence. But he must not be pressed to achieve things, as this would increase the tension.

Caesarean Section after Vaginal Fistula

Q.—*A primipara with small pelvic measurements took some 24 hours to reach full dilatation, and finally, after manual rotation of a persistent occipito-posterior head, had a forceps delivery of a live child. Three days later, despite passing urine normally, she developed a cysto-vaginal fistula. This was successfully repaired five weeks later. She is now pregnant again, three years after the first child. The scar of the repair is sound and of a hard unyielding consistency. In view of the past history and the tough anterior vaginal wall, is the correct treatment to perform Caesarean section at or near term?*

A.—The usual procedure is to advise Caesarean section for cases of this kind. The contracted pelvis may be responsible for another difficult delivery, with a tight fit between the head and the pelvis, so that the old operation scar may be damaged and the fistula recur. The majority of obstetricians would unhesitatingly perform Caesarean section at term in such a case.

Children's Wards and Cross-infection

Q.—*How should a children's ward be designed to reduce cross-infection?*

A.—Cross-infection in a children's hospital or unit can best be countered by including a large proportion of single rooms (up to 50% of the available beds); by small wards of 4 to 8 beds; by good ventilation and lighting; by a sufficiency of wash-hand basins in the wards, sterilizers in the annexes, and modern labour-saving equipment; and, most important of all, by an adequate and properly trained nursing staff. The sources, modes of spread, and methods of control of "hospital infection" should be taught to all nurses early in their career. There can, of course, be no standard pattern of ward, but a modern and well-designed unit has lately been described by Jacoby (*Arch. Dis. Childh.*, 1944, **19**, 26). This unit of 35 beds consisted of one 6-bedded ward, four 4-bedded wards, two 2-bedded wards, and four single-bedded wards, with the usual annexes, milk-room, and *accommodation for nursing mothers*. But design alone will not accomplish much if the administrative and nursing precautions given in detail in M.R.C. War Memo. No. 11 are not put into effect. Thus examination and distribution of cases on admission must be done by an experienced R.M.O.; children under a year must be nursed in single rooms; great care must be taken with the preparation of infant feeds; masks should be worn by nurses and medical staff as required; visitors should be discouraged; and passive or active immunization of patients should be practised whenever practicable.

LETTERS, NOTES, ETC.

Psychiatry in the Services

A medical psychologist writes: The answer to the question on page 283 of the *Journal* of Feb. 24 regarding psychiatry in the Service can hardly go unchallenged. In the first place psychiatry does no include *all* acts of behaviour; that is the province of the wide science of psychology. Psychiatry, as its name implies, means healing, and therefore deals only with abnormalities. Nor can one let go unchallenged the writer's exclusion of the "lack of moral fibre" from the concern of the psychiatrist, for this may, among other things, be due to constitutional disorders such as are to be found in the asthenic type. In any case the writer contradicts himself, for if psychiatry deals with all acts of behaviour, why does he tell the psychiatrist to "stick to his last" and not deal with lack of moral fibre, but to leave that to the executive authorities? Is not this a form of behaviour?

Coloured Film of Casualties

Mr. W. McADAM ECCLES, M.S., F.R.C.S. (London, W.1) writes: Since damage and casualties are still occurring in Southern and sometimes Northern England, though the day of their cessation is drawing near, it is not inappropriate to remind medical officers and others associated with Civil Defence and A.R.P. that the unique coloured film of "Casualties" is still available for exhibition after having been shown to many thousands of workers. Particulars can be obtained from the manager, Mr. J. Magrill, 17, St. Quintin Avenue, London, W.10.

Treatment for Superficial Eye Infections

Dr. SHEILA MILLAR-DANKS (Dulwich Hospital, S.E.22) writes: I read with interest Dr. Graydon Hume's letter (Jan. 27, p. 129) concerning superficial eye infections. I was aware of the benefit of a stable solution of ephedrine and silver vitellinate for nasal use having read the correspondence on the subject in the *Journal* in December, 1943, and January, 1944, but its value for eye infections was new to me, and especially the fact that stabilization of the solution eliminated argyrosis. Although post-anaesthetic conjunctivitis is becoming a rarity due to the increase in the use of closed methods of anaesthesia and decrease in the employment of ether as an anaesthetic agent, it still occurs where the open method of administration is used. Possibly the solution suggested by Dr. Graydon Hume would be efficacious in dealing with the condition.

Corrections

An old Guy's man wishes to register a correction of the item of news published on March 10 at page 353 recording a medical dinner at Delhi. The Director-General, I.M.S., Lieut.-Gen. J. B. Hance, is a Cambridge and Guy's man, not an alumnus of Edinburgh.

The number of cases of pneumococcal meningitis which Dr. El Davis stated had been seen in a sister hospital to his own was eight not eighty as given in the report in the *Journal* of March 17 (p. 379)

BRITISH MEDICAL JOURNAL

LONDON SATURDAY MARCH 31 1945

IMBALANCE OF VITAMIN B FACTORS

PYRIDOXINE DEFICIENCY CAUSED BY ADDITIONS OF ANEURIN AND CHALK

BY

MARION B. RICHARDS, M.A., D.Sc.

(From the Rowett Research Institute, Aberdeen)

In the clinical literature during recent years there have been numerous indications of a certain interrelationship or antagonism between various factors of the vitamin B complex. Pellagrins, after treatment with nicotinic acid, often show signs of beriberi or of ariboflavinosis (Spies, Vilter, and Ashe, 1939; Sebrell and Butler, 1938; 1939; Sydenstricker *et al.*, 1940). There are recorded instances also of converse antagonisms. Thus Bichel and Meulengracht (1941) report a case of pellagra arising after treatment of the Plummer-Vinson syndrome with riboflavin (i.e., vitamin B_2); and Salvesen (1940), Brændstrup (1940), and Lehmann and Nielsen (1939) all found signs of pellagra in patients who had been given large injections of vitamin B_1. There is little doubt that in many of these cases the deficiencies in the diet were multiple, and it is assumed that successful treatment of the predominant deficiency with a single factor of the B complex showed up other deficiencies which had previously been masked. At the same time there is the possibility, in some cases at least, that secondary deficiencies were induced by the excessive dosing with one particular factor of the B complex, and that the unbalanced proportions of the different factors gave rise to a deficiency which was not present under the original conditions. Spies, Vilter, and Ashe (1939) made the significant remark, without apparently realizing its possible implications, that in pellagrins treated with nicotinic acid and continuing on their usual diets, *the associated deficiencies* (i.e., of B_1 and riboflavin) *often became worse.*

One or two attempts have been made, but without much success, to induce symptoms of deficiency of one B factor by excessive dosing with another. Klopp, Abels, and Rhoads (1943) found a transitory increase in urinary excretion of riboflavin in some patients after administration of thiamine (i.e., B_1), but could not induce either clinical or chemical evidence of riboflavin deficiency in these individuals even when large amounts of thiamine were given daily for 73 days. Unna and Clark (1942) could find no evidence of adverse effects on the growth of rats following administration of excess of individual vitamins in the presence of deficiencies of other vitamins of the B complex.

Effect of Overloading with B_2

Recent experiments on rats in this Institute, however, have produced clear-cut evidence of the adverse effects that may be caused by a disturbance of the balance of the vitamin B factors in the diet, and have shown that overloading with one component, B_1, can produce a definite deficiency of another component, B_6. The experiments were designed to follow up a series of which the results were reported a year ago. In studies of the influence of the dietary factor on reproduction and lactation the results showed the beneficial effects on the breeding performance of rats of additions of chalk, dried yeast, and milk to a poor human diet (Richards, 1943). On the other hand, addition of pure vitamin B_1, as aneurin, seemed to have a definitely harmful effect, as the weaning weights of the young rats were low and the mothers were in very poor condition after rearing their litters. It was therefore suggested that caution must be exercised in the addition of vitamin B_1 to a poor diet, and the present experiments were planned to investigate this point more closely. Using a synthetic diet* as basal ration in place of the human dietary of the earlier experiments, vitamin B_1 (as aneurin) was given at 3 levels—low, medium, and high—and these 3 levels were repeated in 3 additional groups which received also a supplement of chalk.

In the growth tests, which lasted from weaning till the rats were mated at about 115 days of age, the chalk group at each level of B_1 intake showed a higher weight increase than the corresponding group without chalk, but these differences were not great. The groups receiving high B_1, both with and without added chalk, were somewhat lower in weight than the corresponding groups on medium B_1, but there was no noticeable difference between the animals in their general condition. Thus the growth tests, like those of Unna and Clark (1942), gave no very marked evidence of untoward effects arising from the variations in the diet. It is generally recognized, however, that a diet which may be reasonably adequate for growth, and even for reproduction, may not be adequate for successful lactation, and the lactation test in these experiments, even when the diet was improved by milk supplements, revealed differences between the groups which had been quite unsuspected from the growth test and the reproduction records. In certain cases the litters failed completely to survive to weaning; in others a few members of the litter survived, but were much below normal weight and in very poor condition; while in some instances litters which were nearly normal in weight and apparently quite healthy suddenly showed the convulsive fits which enabled their condition to be diagnosed as pyridoxine (i.e., B_6) deficiency. Chick, El Sadr, and Worden (1940)

---

* The synthetic diet was planned to be approximately equal in caloric value and Ca content to the original poor human diet, which contained a large proportion of white bread. It consisted of: white flour (untreated with chalk or aneurin) 1,020 g., commercial casein 400 g., dried brewers' yeast 32 g., salt mixture (McCollum 185) 33.3 g., margarine 180 g., radiostoleum (containing 1 g. α-tocopherol acetate in 50 c.cm.) 2 c.cm., KI 0.00616 g., and $MnSO_4.4H_2O$ 0.0616 g. In the groups which received extra calcium, chalk was added in the proportion officially recommended in making "fortified" white bread. A small amount of aneurin was added to the basal diet to make the B_1 content equal to that of the original basal group in the human dietary experiments. In the groups with "medium" aneurin, the amount added was equivalent to the difference in B_1 content between white and national wheatmeal flour, and to the "high"-aneurin groups 10 times this amount of B_1 was given. There were thus 6 groups in the experiment:

I. Basal + low B_1 .. II. Basal + medium B_1 .. III. Basal + high B_1
IV. As I + chalk .. V. As II + chalk .. VI. As III + chalk

The Ca intake for Groups I, II, and III worked out at approximately 0.33 g. per 1,000 Cal., and for Groups IV, V, and VI at 0.81 g. per 1,000 Cal. The B_1 intake for Groups I and IV was approximately 198 i.u., for Groups II and V 554 i.u., and for Groups III and VI 3756 i.u. per 1,000 Cal. The B_1, KI, and Mn supplements were added as dilute solutions daily to the liquid used in making up the ration, which was fed as a stiff paste. In the breeding tests, milk supplements were added to the diet—10 and 20 c.cm. per head respectively to half of each group in the first test, and 20 c.cm. per head in the second test reported the occurrence of fits of an epileptiform nature in rats maintained for long periods on a diet deficient in vitamin B$_6$. The seizures were characterized by hyperexcitability and circular running, tonic-clonic convulsions, and a comatose recovery period. Still more apposite, from our point of view, were the findings of Daniel, Kline, and Tolle (1942), who reported similar seizures in young rats while being nursed by mothers on pyridoxine-deficient diets, the symptoms appearing suddenly towards the end of the lactation period. The syndrome was "characterized by frantic running about the cage, accompanied by loud cries and convulsive seizures," and the symptoms could be prevented or cured by pyridoxine supplements. Patton, Karn, and Longenecker (1944), who studied the incidence of sound-induced seizures, also recently reported the occurrence of spontaneous convulsions in young rats suckled by mothers maintained from parturition on pyridoxine-free diets.

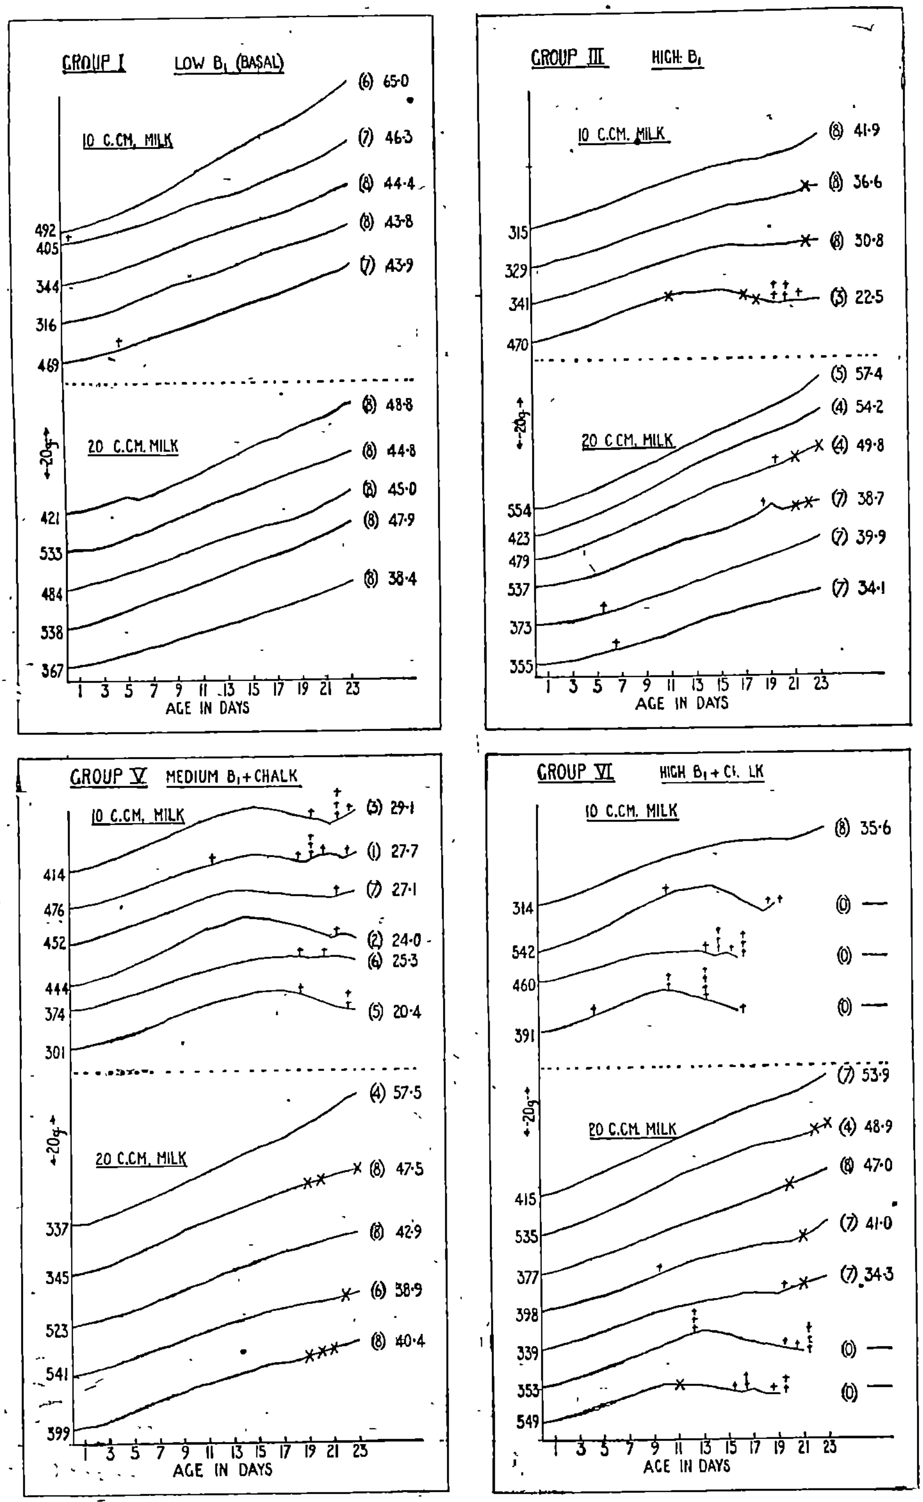

CHART I.—Showing average weight in grammes per rat from birth to weaning for individual litters. At the left of each graph is the number of the doe. At the right of each graph, in brackets, is the number of young reared. At the right of each graph, unbracketed, is the average weaning weight of the litter. † indicates the death of a rat. × indicates the occurrence of fits.

These descriptions fitted so exactly the symptoms observed in our young rats that there seemed to be little doubt that we were dealing with a conditioned pyridoxine deficiency, since the only variables in the diet were the vitamin B$_1$ and chalk. Comparison of the groups showed that the lactation performance deteriorated as the level of B$_1$ increased, and that conditions were made worse by the addition of chalk. At each level of B$_1$ the group receiving chalk was worse than the corresponding group without chalk. Thus the best group was Group I—the basal group with low B$_1$ and no added chalk. The litters were approximately normal in their weight curves, whether the milk supplement was 10 or 20 c.cm.; and convulsions were not observed in any of the litters. The worst group was Group VI, with extra chalk and high B$_1$. In this group 10 c.cm. milk was quite inadequate to ensure successful lactation, only one litter surviving to weaning stage. In the section of this group receiving 20 c.cm. milk, 5 litters reached weaning stage, with approximately average weaning weight, but 6 of the 7 litters in the group showed the typical convulsions. In Group V, which had extra chalk with medium B$_1$, 10 c.cm of milk again proved insufficient, although the performance was better than in the high B$_1$+chalk group with 10 c.cm. milk. Representatives of 6 litters reached weaning stage, but there were many deaths during lactation, and the few survivors were low in weight and in poor condition. Convulsions were not observed in rats which were very puny and sickly. With 20 c.cm. of milk the lactation performance was again much improved. Deaths during lactation were reduced to zero, and weaning weights were approximately normal, but the characteristic fits were observed in 3 litters. Group III, with high B$_1$ and no added chalk, was about equal in performance to Group V, with medium B$_1$+chalk, and much better than the group with high B$_1$+chalk. One instance of convulsions was observed in Group II, with medium B$_1$ and no chalk and two instances in Group IV with low B$_1$+chalk. The lactation performances of 4 of the groups are summarized in Chart I which shows the average weight curves of the individual litters from birth, and indicates the occurrence of convulsions. Groups II and IV are not included, as the weight curves showed little departure from normal.

The breeding test was repeated, to obtain confirmation of these results and to test whether the onset of convulsions in the worst groups could be prevented by giving the does a supplement of pyridoxine from parturition. This supplement was given to half the does in Groups III, V, and VI. All rats in this test received a supplement of 20 c.cm. milk, since the 10-c.cm. supplement had proved insufficient in certain groups to bring the young to weaning and convulsions seemed to occur more readily when the young rats were fairly normal in weight. Chart II gives the results for Group VI, receiving high B_1 + chalk, from which it will be seen that the previous findings are amply confirmed. Seven out of eight litters showed the characteristic convulsive fits, several of them having repeated attacks. Although fits were not actually observed in the eighth litter, it seemed probable that they may have occurred (possibly overnight) when no observer was present, for it was noted that the general condition of the young in this litter at weaning was very similar to that of another litter in the group in which fits had been observed day after day. Moreover, the weaning weights of the young in these two litters were practically identical—38.3 and 37.8 g.

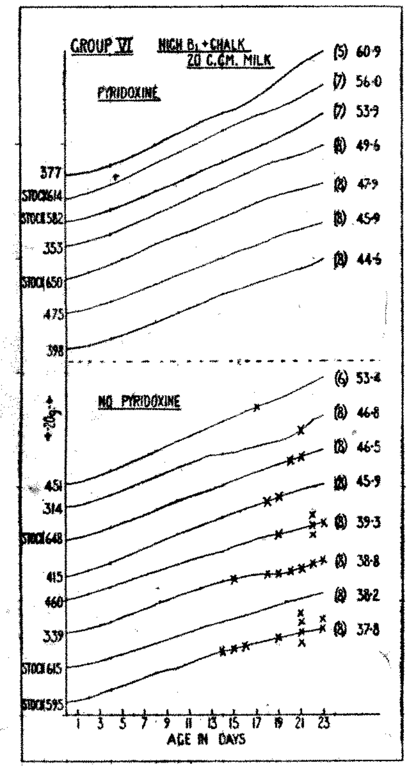

CHART II.—The weight graphs in the upper half represent litters from does which received a daily supplement of 40γ pyridoxine from parturition. The graphs in the lower half represent litters from does which received no pyridoxine. "Stock" indicates that the doe was a stock rat placed on the experimental diet two weeks before mating.

Pyridoxine Supplement.—Seven does in this group were given a pyridoxine supplement of 40 microgrammes daily from parturition, and none of their litters showed convulsive fits. The young progressed quite normally, and the average weaning weight was 49.7 g., as against 41.9 g. in the section of the group which received no pyridoxine supplement. In this experiment also the group with medium B_1+chalk was approximately equal to that with high B_1 and no chalk. In each of these groups 2 litters showed fits, and again not a single fit was observed in litters the mothers of which received pyridoxine supplementation.

It may be noted that a slight difference is observable through all the groups in this test when compared with the corresponding groups in the previous breeding test. Fresh supplies of flour, casein, and dried yeast had to be used in the repeat experiment, and it is unlikely that the new supplies would agree exactly with the old in their contents of all the B factors. A decrease in the B_1 content of the basal ration, or an increase in the B_6 content, or both, would tend to minimize the lack of balance of the B constituents, and the findings of the second test are consistent with such a difference in the basal ration. The lack of balance is somewhat less than in the first test, so that the occurrence of fits in any one group is less pronounced than in the same group of the previous experiment. Thus in Group III (high B_1 with no chalk) only 2 litters showed fits, although 5 litters were affected in the previous test, and no instance of fits was noted in the second test in either Group II or Group IV. But the worst groups come in the same order as before, and the fits were entirely prevented in all groups when pyridoxine was given.

Comment

It seems abundantly clear, therefore, that pyridoxine deficiency was the cause of the symptoms observed, that this deficiency was induced by excess of vitamin B_1 and by excess of chalk, and that the effect was enhanced when both vitamin B_1 and chalk were present in excess. Patton and colleagues (1944), who used two pyridoxine-deficient diets in their experiments, one containing much higher amounts of thiamine, riboflavin, and pantothenic acid than the other, found fewer spontaneous seizures in litters from mothers receiving the smaller amounts of the B vitamins. This is in accordance with our findings in regard to B_1.

While it is a deficiency of B_6 that has become primarily obvious in our experiments, it seems likely that deficiencies of other B factors may also have been induced by the excess of B_1. It happens that pyridoxine deficiency produces this spectacular effect in the young rats, and thus can be very readily recognized when other deficiencies may be overlooked. As a matter of fact, skin lesions, which developed during the mating and lactation periods in practically all the females of Groups V and VI, indicated the presence of some deficiency other than that of pyridoxine. The lesions of the extremities which are said to be characteristic of pyridoxine deficiency did not appear, but there was loss of hair on parts of the body, which might possibly be indicative of a B_2 deficiency, and numerous body sores. The bald patches occurred mainly on the forehead and round the ears, and in some cases the under side of the body was practically denuded of hair. The body sores took the form of isolated septic spots, with loss of surrounding hair. György (1934) and others (e.g., Chick *et al.*, 1935) have shown that if the diet of rats is deficient in both B_2 and pyridoxine the florid dermatitis specific for B_6 deficiency does not become evident until B_2 is supplied. The amount of dried yeast in the diet was intentionally kept at a somewhat low level, to avoid masking any adverse effects of the additions of vitamin B_1. It is thus possible that the supply of B_2 was suboptimal, and liable to be converted to a definite deficiency by excess of B_1, just as happened with pyridoxine.

The high dose of vitamin B_1 given in our experiments is, of course, far in excess of the amount likely to be found in any ordinary human diet, and the amount of pyridoxine in an ordinary mixed diet will probably be such that there is little risk of a deficiency being induced by the amount of B_1 present. Danger may lie, however, in the present-day tendency to prescribe vitamin B_1 somewhat indiscriminately, as a dietary adjunct and to give large doses of B_1 orally or by injection in the treatment of various diseases. It is precisely in such cases, in which the patient is probably on invalid diet that is liable to be unbalanced, that a large excess of B_1 may entail unexpected and dangerous results. In the case described by Brændstrup, for example, the patient, a chronic dyspeptic treated with ulcer diet, was given large injections of vitamin B_1, totalling 220,000 i.u. in 3 weeks. When signs of pellagra developed, treatment with a preparation containing the entire B complex permitted recovery. Apart from the development of pellagra, untoward symptoms of various kinds have been recorded after dosing with vitamin B_1. Steinberg (1938), who treated cases of chronic arthritis with large doses of vitamin B_1, records that in a few patients vitamin B_1 therapy caused "typical lesions of herpes zoster," irritation of the peripheral nerve plates, and spasm of smooth muscle. The pain and irritation ceased when B_1 therapy was withdrawn. Leitner (1943) also describes two cases in which injection of pure vitamin B_1 over long periods produced unfavourable effects. In one case the symptoms resembled those of thyroid overdosage, and included insomnia, headache, giddiness, and palpitation. It may well be, in view of our results, that such untoward effects are evidence of some vitamin deficiency induced by the large excess of the single vitamin.

Little is known as yet regarding human requirements of pyridoxine, but some results recorded by Spies, Bean, and Ashe (1939) are of interest. They found that 4 patients who had been treated successfully for pellagra and beriberi, but who remained on their deficient diets, complained of such symptoms as extreme nervousness, insomnia, irritability, abdominal pain, weakness, and difficulty in walking. All the symptoms disappeared within 24 hours of an injection of 50 mg. of pyridoxine. Later, Spies, Ladisch, and Bean (1940), studying the urinary excretion of B_6 in human subjects, found indications of B_6 deficiency in patients suffering from other clinical deficiency diseases. It is thus evident that pyridoxine deficiency can arise in man under certain circumstances.

It is becoming increasingly recognized that in the treatment of pellagrins with nicotinic acid it is essential to provide other members of the B complex and to prescribe a liberal and well-balanced diet. Our experiments would suggest the necessity for adopting a similar procedure for other B factors, and in particular, when B_1 therapy is indicated, for supplying the whole B complex instead of the single vitamin. It was suggested in the previous paper (Richards, 1943) that the improvements effected in a poor human diet by means of such simple supplements as inorganic calcium, milk, and dried yeast provided a useful pointer for the post-war feeding of the starved populations in Europe. The present results emphasize the need for caution in any attempt to improve the diet of these populations by indiscriminate addition of large supplements of single synthetic B vitamins.

DUCT PAPILLOMATA OF THE BREAST

A PLEA FOR CONSERVATIVE TREATMENT

BY

CECIL P. G. WAKELEY, C.B., D.Sc., F.R.C.S.
Temporary Surgeon Rear-Admiral to H.M. Fleet; Senior Surgeon, King's College Hospital and West End Hospital for Nervous Diseases; Consulting Surgeon to the Maudsley Hospital and to the Royal Navy

There is too great a tendency to-day to regard duct papillomata of the breast as malignant or potentially malignant, and therefore requiring amputation of the breast. To my mind it shows a lack of thought, of experience, and of a thorough examination of every breast removed, when such opinions are held. Local amputation of the breast is an easy operation, and it is wishful thinking to say that because a young woman has a blood-stained discharge from the nipple the breast should be removed owing to the possibility of cancer supervening. It is quite true that a blood-stained discharge from the nipple may be caused by carcinoma, chronic cystic mastitis, or papilloma: it is the responsibility of the surgeon to make a differential diagnosis of these three conditions.

Duct papillomata are nearly always found in the larger ducts, and are therefore situated beneath the nipple or the areola. The majority of these tumours are single, but in some cases multiple papillary growths are to be found in the ducts. The common single papilloma often has a stalk, and some pathologists have termed them "single-stalk" papillomata. They always occur beneath the nipple, and frequently cause bleeding from it.

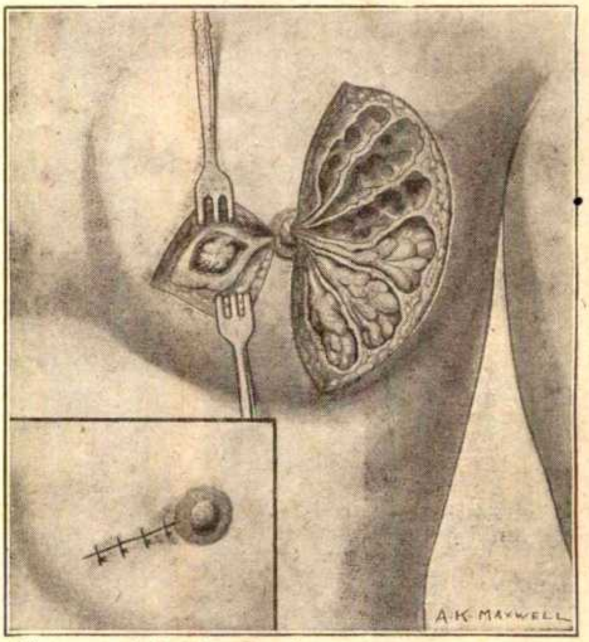
It is difficult to be dogmatic about the common age when symptoms develop, but it can be said that duct papillomata are uncommon before the age of 25, although I have removed one from the breast of a girl aged 20. A small proportion of patients have papillomatous growths elsewhere, the commonest site being the skin.

The clinical course of these cases is interesting, as the papillomata grow very slowly and may continue for many years. The haemorrhagic discharge from the nipple is intermittent, and may be serous with no sign of blood. At times a small tumour may be felt in the region of the nipple. This swelling may be tense or soft, and may entirely disappear after a discharge of blood-stained fluid from the nipple.

In many cases the thickened duct can be felt by careful palpation; quite often it is situated under the areola, and pressure on it will cause a haemorrhagic discharge from the nipple. There is no sign of any hardness or infiltration, such as would be felt if a carcinomatous condition had supervened on the papilloma.

Treatment

Every case must be examined carefully and at definite intervals until it is certain that a dilated duct can be felt. When this is established a local excision of the dilated duct, with the papilloma, can be undertaken (see Fig.). An incision is made radiating from the nipple over the dilated duct. The skin edges are held apart, the cystic dilatation is opened, and the intracystic papilla is completely excised. The operation is simple, and no damage is done to the ducts on either side. The skin incision is closed with a few interrupted sutures, and when healed is hardly noticeable. Every papilloma excised should be examined microscopically for any evidence of malignant disease. The patient should be examined at three-monthly intervals during the first year; after this time a yearly examination will suffice.



Diagrammatic drawing of an intracystic duct papilloma. The outer side of the breast is dissected to show the lactiferous ducts during the period of lactation. Inset: the skin incision united by sutures.

Having performed this operation on 52 cases during the last 30 years I have no doubt that it is the very best form of treatment. What are the alternatives? They are radiotherapy and amputation of the breast. Radiotherapy is usually of little use in curing the condition. The papillomata are not radiosensitive, and at the best fibrosis of the rest of the breast occurs; this is often painful, and produces a functionless breast.

Local amputation of the breast in young women produces a very unsatisfactory state of affairs. The patients become introspective, worry a lot, and tend to become chronic invalids. Many drift to the out-patient departments of the neurological hospitals. I have case reports of 20 unmarried women under 30 years of age who have been subjected to local removal of one or both breasts because of a history of a blood-stained discharge from the nipple. These women are afraid to marry because they consider that they are not normal. This state of affairs must not be allowed to continue, as it means a life of constant misery.

The following up of operation cases is most important if we are to get a clear idea of the real value of conservative surgery. Of my 52 cases of duct papilloma of the breast I have "follow-up" records of 35; six patients are abroad and I cannot trace them. However, the clinical history of three cases will show the real advantage of conservative surgery for duct papilloma.

Case Histories

Case 1.—A nurse, aged 24, who had just finished her training in a London hospital, was seen in July, 1915, with a history of a blood-stained discharge from the left breast for some nine months. Nothing could be felt on examination and no discharge was visible from the nipple. The patient was told to come and see me when there was any further discharge from the nipple. In Sept., 1915, she came again, and a small cystic lump could be felt just lateral to the nipple in the lower and inner quadrant of the breast. A slight blood-stained discharge could be expressed from the nipple. Operation was undertaken, and a small intracystic papilloma was excised. The papilloma had a definite stalk, and microscopically was quite innocent. The patient left hospital a week later. She was seen in 1919 before her marriage, as she was concerned about the effect of pregnancy on the breast. The breast was quite normal, and there had been no discharge from the nipple since the operation. The patient was reassured that no ill effects would supervene if pregnancy took place. She was seen again in 1936 because of cholecystitis due to gall-stones. She had five children—three boys and two girls—and had breast-fed all of them without any difficulty whatever. Cholecystectomy was carried out in July, 1936, and recovery was uneventful.

Case 2.—A married woman aged 32 was seen in Jan., 1920; she was sent to me to have her right breast removed because of an intermittent blood-stained discharge. She was a big woman with large firm breasts. A small lump the size of a pea could be felt in the lower and outer quadrant of the breast. She was prepared to have the breast removed, but was advised to undergo excision of the lump instead. Local excision of the papilloma was carried out and the growth was found to be innocent. The patient was last seen in 1939, when she was in good health; the breast was quite normal, although somewhat atrophic. Her periods had stopped some three years previously.

Case 3.—An unmarried woman, aged 26, a well-known golfer, was seen in 1922 because of a blood-stained discharge from the left nipple. There was little to make out on clinical examination, and the patient was told not to worry and to forget about her breast. She was seen in 1923 and again in 1924, and on neither occasion could anything be felt in the breast, although there was a slight intermittent discharge of blood-stained fluid from the nipple. When seen in May, 1925, a small lump could be felt in the lower part of the breast just below the nipple. This was excised, and proved to be a simple papilloma. Six months later the patient married and was not seen again till 1932, when her child, aged 6, was operated upon for appendicitis. Her breasts were then quite normal and there had been no discharge from the nipple since the operation. She had not breast-fed her child, as her doctor thought it might cause trouble in the breast. This idea, which still prevails in some quarters, is quite erroneous.

Conclusion

These three cases clearly demonstrate the value of conservative surgery in the treatment of duct papilloma of the breast. Every hospital of any size has specimens of small innocent papillomata because of which the breast had been removed. Conservative surgery will not provide such nice museum specimens, but it will produce contented and very thankful patients.

B. Levant (*J. Urol.*, 1944, **52**, 63) records a fatal case of sarcoma of the penis in a negro aged 29. Deep *x*-ray therapy was beneficial. Biopsy from an inguinal gland, though confirmatory of metastases, hastened the spread of the tumour, with general systemic failure.

"NEUTRAL PROFLAVINE SULPHATE" (MONOSULPHATE OF 2:8-DIAMINO-ACRIDINE)

ITS LOCAL ACTION IN INFECTED WOUNDS INVOLVING BONE

BY

J. F. HEGGIE, M.B., B.Sc.Glas.
Surg. Cmdr., R.N.V.R.; Bacteriological Specialist

G. B. R. WARNOCK, M.B., M.R.C.P.Ed.
Capt., R.A.M.C.; Graded Pathologist

(From a General Hospital)

It has been realized for a considerable time that the high acidity of proflavine sulphate *B.P.* is a serious drawback, and various methods have been suggested for countering this, such as a preliminary neutralization with sodium bicarbonate or the addition of a buffering salt. There is now available, however, "neutral proflavine sulphate," which possesses all the activity of the *B.P.* salt and yet gives a neutral solution. The relationship of neutral proflavine sulphate to proflavine sulphate *B.P.* may be compared with that of quinine sulphate to quinine bisulphate—i.e., the neutral sulphate has one equivalent of acid, while the *B.P.* salt contains two equivalents. In a 0.1% solution neutral proflavine sulphate is stated to have a *p*H of 6.5, as contrasted with *p*H 2.5 of proflavine sulphate *B.P.* Our brief experience with a sample of neutral proflavine sulphate indicates, however, that its action towards the tissues is the same as that of proflavine sulphate *B.P.*, and consequently, like it, should be used (1) in small doses of from 0.2 to 0.5 g. in discharging wounds, and (2) diluted to 0.5% in sulphathiazole powder for local application to wounds subjected to fresh débridement. We would also suggest that the optimum concentration of proflavine sulphate *B.P.* in sulphathiazole–proflavine powder is 0.2%, rather than the strength of 1% at present employed prophylactically in "debrided" wounds.

The cases treated were with us for only a short time. They comprised gunshot and similar wounds with compound fractures (often comminuted) which had been infected and relatively untreated for from six months to two years. The majority had had repeated sequestrectomies, with, in some instances, sulphonamides locally and/or orally in support. By the time of our observations general nutrition was restored; none of the patients were more than slightly anaemic (less than 80% Hb). Neutral proflavine sulphate powder, sterilized as are the sulphonamides, was applied to the wound area at the time of the last sequestrectomy and the wound lightly packed. In a few cases it was applied 2 to 14 days after sequestrectomy, and in others it was inserted into sinuses from the depths of which sequestra had been removed earlier. Thus the powder was applied to surfaces with granulations forming and established and with exudate in varying amount, as well as to wounds "debrided" afresh, with curetted and guttered bone, curetted sinuses, etc., in which no granulation tissue and little exudate or pus was present.

Technique of Treatment

At first, having regard to the relatively neutral character of neutral proflavine sulphate, doses of from 1 to 5 g. were applied, the former to small and the latter to large wounds. Many patients complained of some burning pain, which during the first 24 to 48 hours was accompanied by moderate pyrexia (101–102° F.), partly attributable to surgical measures. Locally, the soft tissues around the wound were inflamed, and brawny oedema extended for a short distance. The immediate wound margin was of firm, rubber-like consistence. On removing the excess neutral proflavine sulphate on the 4th, 6th, or 10th day the wounds were dry and the appearance of the walls everywhere up to but not involving the skin margins was that of "tanning"—superficial coagulative necrosis—to a depth of 2 to 4 mm. This was most pronounced in freshly "debrided" wounds, which were relatively dry, and less pronounced where there had been some bleeding and exudation following operation; and absent, or almost so, in cases with discharging sinuses. In these latter instances the main coagulative effect of neutral proflavine sulphate had been expended on protein precipitation in the exudate—serous, sero-sanguineous, or purulent—which could thus be said to have a "sparing" effect on the subjacent tissues.

Generally, the results obtained were not good; the doses used, even in the case of the larger wounds, were much too great, and the wounds suffered an added immediate chemical inflammation of 1 to 4 days' duration. When, however, the doses employed were smaller but still twice or thrice the recommended maximum of 0.5 g. suggested for proflavine sulphate *B.P.*, the results were more satisfactory. The treatment of sinuses met with varied success, and, as in the case of the major wounds, this depended largely on the completeness of surgical removal or reduction of the bulk of the infection. This last is a fundamental surgical principle which scarcely need be illustrated. Nevertheless, our experience is that it is not always followed, as it does not appear to be generally understood that all chemotherapeutic treatment is but an adjuvant to surgical procedure; and whether the agent be penicillin, an amino-acridine, or a sulphonamide, the chance of success attending its use is in varying proportion to the degree of completeness of, and to the interval of delay of application after, radical surgical treatment. This notwithstanding, we had hoped that with neutral proflavine sulphate a greater latitude would be observed on account of the greater solubility of this salt in the tissue fluids; but this was not so, as the following case illustrates:

Case I

Male aged 26. Gunshot wound right leg 9 months previously. Two months after injury: osteomyelitis lower third right tibia with sequestrum and involucrum; treated in plaster. 4th to 9th month: wound opened, explored, and drained at intervals. 8th month: inner wound broke down; wound opened up, two sinuses guttered, two cavities found in tibia and levelled up; sterile neutral proflavine sulphate powder, 5 g., applied, lightly packed; light plaster cast applied.

After operation patient complained of moderate pain for 24 to 36 hours. No fever. 6th day: excess neutral proflavine sulphate removed; whole area showed "tanning" (superficial coagulative necrosis); margins slightly indurated. 22nd day: saucerized wound, neutral proflavine sulphate coagulum adherent in parts; pus welled up from posterior part of tibia—another cavity probably existed. 32nd day: outer wound broke down and discharged; advisability of amputation considered. 37th day: outer wound discharge less. Patient later transferred.

In this case it is apparent that the entire extent of the diseased bone had not been defined; later, *x*-ray examination showed diffuse osteomyelitis of the lower two-thirds of the tibia. The remaining foci in the sclerotic bone had not been sterilized by the diffusion of neutral proflavine sulphate from the depot in the under aspect of the "coagulum," because either the organisms were inaccessible or the amount of dye diffused was not sufficient.

In all of the cases in which superficial coagulative necrosis or "tanning" occurred the rate of healing was definitely impaired, despite the fact that the wound was sterile when the "coagulum" remained dry. Thus in a wound which appeared likely to close completely at a reasonably early date, despite slight to moderate degrees of infection, a stationary period resulted from the damage to the superficial layers, and was followed by a period of slow recovery to the previous rate and eventual healing. This is illustrated in the following case:

Case II

Male aged 23. Gunshot wound left leg, with compound-fracture of tibia and fibula of 8 months' duration. Treated in plaster cast within 14 days of injury. Five weeks after injury: sequestrum of end of upper fibular fragment removed; exuberant granulations cut away; sulphathiazole applied locally; entrance wound 4 in. by 2 in., exit wound 6 in. by 3 in. 4th month: sequestrectomy. Later, patient up and walking, foot-drop improving, wounds healing. 6th month: sequestrectomy of tibia through old wound. Two days later, on arrival of neutral proflavine sulphate, 1 to 1.5 g. of the sterile salt was put into the open wound. During the next four days the patient complained of severe burning pain and there was oedema of the wound area; slight pyrexia. Excess neutral proflavine sulphate removed 10 days later, when appearances of "coagulation" were seen. Four weeks after sequestrectomy: healing slowly; shallow eschar-covered "ulcer," 2 in. by 1/2 in., remains. Six weeks after sequestrectomy: almost healed.

In the next case, despite the fact that neutral proflavine sulphate was not applied until two weeks after major surgical treatment, the discharge dried up and the wound healed, chiefly because of the completeness of the surgical procedure and the relatively limited nature of the infection in the humeral head; and, to a less extent, on account of the "sparing" action of the exudate—coagulation or tissue damage being minimal despite the relatively large amount of neutral proflavine sulphate employed.

Case III

Male aged 30. Gunshot wound right shoulder, involving the shoulder-joint, with fracture of humerus and scapula, sustained one year previously. Put up in plaster spica "soon" after injury. Bony ankylosis. Discharging sinuses for many months, increasing latterly. 12th month: sequestrectomy and curettage, much soft bone removed from humeral head; tube drains; skin stitched. One week later: pain on movement, slight discharge. 2nd week: tubes removed, sterile neutral proflavine sulphate, 1 to 1.5 g. powder, inserted into cavity in head of humerus. No great inflammatory reaction, but slightly increased discharge. 3rd week: wound dried up; appearance of "tanning" minimal. 6th week: almost healed. 8th week: healed.

It will have been observed that in none of these cases was any sulphonamide—e.g., sulphathiazole—given orally to supplement the local chemotherapeutic treatment. This is at variance with our recommendation with regard to the necessity for both oral and local administration of sulphathiazole at the time of full surgical treatment in like cases of bone infection (Heggie, Kendall, and Heggie, 1942), but in the present instance the omission was intentional, so that the value of the neutral proflavine sulphate alone might be assessed.

Bacteriostatic and Bactericidal Action

After the application of neutral proflavine sulphate powder the wounds were not necessarily always sterilized; this varied with the kind of wound, its state, the amount of discharge, and, as regards neutral proflavine sulphate, the degree of coagulation produced, and the resulting availability in solution of that salt from the depot in the coagulum. Sterility was most certain to result when application was made at the time of full surgical treatment and the "tanning" effect of neutral proflavine sulphate was distinct—that is, when the infected focus was removed and remaining surfaces were sterilized by coagulation. In other cases, slightly to moderately infected and discharging, reduction of the bacterial flora first, with sterility later, was not uncommon. This was to be expected, and is in keeping with the known slow bactericidal effect of the amino-acridines: their chief action is bacteriostatic; they limit bacterial proliferation, while leucocytic and tissue defences play their part. In wounds of the thigh or gluteal region, reinfection with coliform organisms occurred—and in this regard we would emphasize the need (sometimes overlooked) for attention to the marginal skin of wounds, and the peculiar desire of some folks to change dressings too often. In other wounds, infection with *Proteus* and *Ps. pyocyanea* remained: these organisms were most numerous, and *Ps. pyocyanea* was most persistent. Raven (1944) has reported like changes in the bacterial flora of infected wounds when using proflavine sulphate *B.P.*

In vitro the bacteriostatic and bactericidal actions of neutral proflavine sulphate and proflavine sulphate *B.P.* are practically identical, though the latter is slightly more active (next immediate tube in a series of falling dilutions). With a series of six freshly isolated strains of *Staph. pyogenes* and *Esch. coli*, and using a large inoculum—1 million in 10 c.cm. of broth—neutral proflavine sulphate was bactericidal within 24 hours, to staphylococci at 1 in 2,000 and to the coliform organisms at 1 in 4,000. With similar inocula in broth, organisms from the series of wounds treated with neutral proflavine sulphate were killed within 24 hours by the following dilutions of that salt:

Ps. pyocyanea	1/1000 and 1/2000
Staph. pyogenes ..	1/2000 (1); 1/4000 (4); 1/6000 (1)
Coliforms	1/4000 (1); 1/6000 (1)
Staph. albus	1/12,000 (2)

The efficiency of neutral proflavine sulphate can be judged easily from consideration of the following facts:

(*a*) The bacteriostatic effect of the proflavine salts (in serum) on *Staph. aureus* and *B. coli* is evident at dilutions of 1/200,000 and 1/100,000 respectively (Browning *et al.*, 1917).

(*b*) Neutral proflavine sulphate is soluble in serum to the extent of 1 in 300.

(*c*) The amino-acridines are not rendered ineffective by pus or the breakdown products of tissues.

It is obvious, however, that neutral proflavine sulphate must be available in solution to the tissues, and its concentration in the tissue fluid should be such as rapidly to effect complete bacteriostasis, without damaging the tissues even slightly.

Discussion

It is obviously important to consider the solubility of any antiseptic. Albert and Gledhill (1943) treated a specimen of 2:8-diamino-acridine with one equivalent of sulphuric acid and obtained a "neutral sulphate" which would remain in 25% aqueous solution at 15° C. for a week. The solubility of amino-acridines, however, as those authors point out, is easily affected by small amounts of impurities; and the purified salts do in fact usually show a decreased solubility. Our sample of neutral proflavine sulphate, which has been shown by analysis to have the correct acid-base ratio, will dissolve to the extent of 1 in 4 in warm water, but the solution begins to crystallize after 24 hours at 15° C. The *p*H of a 0.1% solution is 6.5, compared with *p*H 6 reported by Albert.

When serum is added to neutral proflavine sulphate powder in a test-tube the powder slowly becomes moistened and syrupy, and the supernatant serum reaches dye-saturation point (0.3%) within 6 to 12 hours. When, however, serum or albumin in 4% solution is added in equal volume to a range of saline dilutions of neutral proflavine sulphate precipitation at once occurs in the 4.5% to 0.6% solutions, being most pronounced in the range 4.5% to 1%, and showing proflavine crystals as well as protein precipitates in the 4.5% to 2.0% range. If fresh serum be now added to the combined precipitates or to the protein precipitate alone, the serum takes up the dye, to saturation or equilibrium, without further precipitation, and most of the dyestuffs may thus be recovered. Similar precipitation of protein occurs with saline solutions of proflavine sulphate *B.P.* in the range 0.75% (maximum solubility) to 0.25% (trace), but not in the 0.2% solution. Proflavine sulphate *B.P.* is highly acid, with a *p*H 2 in 0.1% water, being extensively hydrolysed in solution; so it is possible that neutral proflavine sulphate is dissociated to some extent in saline solution and the *p*H value of the stronger neutral proflavine sulphate saline solutions is nearer the isoelectric point of plasma proteins (*p*H 4.5); alternatively, in the stronger and more acid solutions the serum proteins behave as an alkali and are precipitated as sulphates, being linked to the sulphuric acid radical dissociated from neutral proflavine sulphate.

Now we can appreciate what occurs in wounds treated with amino-acridine powders. Serous, sero-sanguineous, and purulent exudates protect underlying tissues and granulations from coagulation necrosis (the protein-precipitating action of proflavine sulphate *B.P.* and neutral proflavine sulphate) by their proteins suffering precipitation—greatest when the water content is high enough to permit of solution of the sulphates to protein-precipitating concentration, and least, or absent, when the fluid (non-cellular) portion approximates serum in composition; for, it will be recalled, the powder dissolves slowly in serum without any precipitation. Thus, in one of our unsuccessful cases neutral proflavine sulphate powder was almost all recovered from a protein–proflavine "cast" of the discharging through-and-through sinus treated. When proflavine sulphate *B.P.* is applied to a freshly "debrided" wound some of the powder dissolves in the oozing blood and serum to a maximum concentration of 0.3%; but much more dissolves in the tissue fluid, where, in lower protein and greater water and electrolyte content, it is more easily soluble—to 1%, 2%, or more in the case of neutral proflavine sulphate and approximating 0.4% to 0.6% when proflavine sulphate *B.P.* is used. Being thus above the critical levels of 0.5% (neutral proflavine sulphate) and 0.2% (proflavine sulphate *B.P.*), precipitation of the protein (coagulation necrosis) of the proximal tissue cells occurs to a depth of 2 to 4 mm. Depending on the concentration of proflavine first attained, a certain amount of fine crystals of that substance also may be deposited. Clinically, in proportion to the amount of proflavine present to excess in wounds, an inflammatory reaction is set up, with capillary haemorrhages and oedema. This oedema occurred in many of our cases, and lasted for one to two days as a rule, although occasionally it took four days to subside. In the guinea-pig 50 mg. of neutral proflavine sulphate powder, suspended in saline and injected subcutaneously in the abdominal wall, resulted in local haemorrhagic necrosis of muscle and much inflammatory oedema of the loose areolar tissues; while contiguous subjacent bowel wall became necrotic, and the liver showed superficial haemorrhage and necrosis.

From our observations we cannot recommend the use of the sulphates of proflavine as pure powders in the treatment of wounds except under certain conditions. In this we are in agreement with a like statement of Russell and Falconer (1943), made as a result of their animal experiments with the three amino-acridines—proflavine sulphate *B.P.*, 2:7-diamino-acridine, and 5-amino-acridine. A reason for the excellent results obtained by Mitchell and Buttle (1942) with proflavine sulphate *B.P.* in infected wounds of 5 to 12 days' standing is afforded by the "sparing" action of the purulent exudate present at that time and the fact that the infection was not yet "established" in bone. This is also true of similar cases recorded by Raven (1944). With neutral proflavine sulphate a like result is shown by our Case III. This is the only type of case in which it would be permissible to use the proflavines as powders, alone; for if the dose were limited to 0.2 to 0.5 g. for each application no added chemical inflammation or coagulation necrosis would be likely to occur. (There is no point in using sulphathiazole–proflavine powder in such cases. It would be of practically no additional value as a bacteriostatic, for the pus and tissue-breakdown products would surely neutralize the sulphathiazole.)

As regards the prophylactic use of the proflavine sulphates, we would suggest that for local application in powder form they be diluted with sulphathiazole to 0.5% in the case of neutral proflavine sulphate and 0.2% for proflavine sulphate *B.P.* The latter dilution is one-fifth of the concentration advocated by McIntosh and Selbie (1943) for the treatment of war wounds in general and of gas gangrene in particular; but we suggest these concentrations as they are the highest possible of employ if coagulation necrosis is to be avoided and tissue damage kept to a minimum. By lowering the concentration of the proflavine sulphates to these levels their bactericidal and bacteriostatic values are practically not reduced, for the amino-acridines are rapidly bactericidal at a concentration of 0.2% (Garrod, 1940).

We have remarked already (Heggie *et al.*, 1942) on the practical difficulty of ensuring the regular distribution, and the availability for solution, of sulphonamide powders in irregular wound cavities, to combat which we discarded the powder form in favour of a saline–glycerin–tragacanth sludge as a vehicle for sulphathiazole. Now in the case of neutral proflavine sulphate we employ a simple pouring tragacanth gel, containing a 0.5% saline solution of the drug, for use in the prophylactic treatment of wounds. The good results obtained to date may be attributed to the early stage at which compound fractures and flesh wounds have been received. Nevertheless, healing has not been impaired, bacteriostasis has been good, and we consider the use of this method worthy of further clinical trial. At most, 10 c.cm., containing 0.05 g. of neutral proflavine sulphate, has been used in any one wound at any one time.

Summary and Conclusions

Neutral proflavine sulphate has a place with the acid proflavine sulphate *B.P.* in the treatment of recently infected discharging wounds. When these amino-acridines are so used as pure powders, alone, and in small doses of from 0.2 to 0.5 g. (repeated at 5 to 15 days' intervals, if and as necessary), infection is reduced, discharges diminish and soon cease as the wound becomes dry, and healing proceeds. In such cases the proflavine sulphates produce little or no tissue necrosis, owing to the "sparing" action of the exudates, in which, after probably some measure of protein precipitation, they dissolve and diffuse to the tissues in effective bactericidal and bacteriostatic concentration.

When applied to freshly "debrided" wounds, or wounds with little exudate, a chemical inflammation occurs, attended by superficial coagulation necrosis to a depth of 2 to 4 mm., due to solution of the sulphates in the tissue fluid to a protein-precipitating concentration. Healing, at first arrested, is generally retarded, occurring under or after separation of the eschar. In saline solution the lowest concentration of these salts at which protein precipitation occurs is 0.6% and 0.25% of neutral proflavine sulphate monoacid and proflavine sulphate *B.P.* respectively. It is suggested, therefore, that the optimum concentration of these salts in a sulphathiazole–proflavine powder, for use prophylactically in war wounds, should be 0.5% for neutral proflavine sulphate and 0.2% for proflavine sulphate *B.P.*, and, having regard to the difficulty of effectively applying powders to irregular wound cavities, saline-tragacanth gels of either of the proflavine sulphates, alone, and in the strengths mentioned, might be employed instead.

Our thanks are due to Col. F. Holmes, O.B.E., for his kind permission to carry out this investigation in the hospital under his command; and to Dr. R. P. Liston, of Imperial Chemical (Pharmaceuticals) Ltd., for providing the sample of neutral proflavine sulphate. To Major O. N. Bailey, R.A.M.C., surgical specialist at the hospital, and Capt. H. R. W. Lunt, R.A.M.C., graded orthopaedic surgeon to the hospital, our thanks are also due for the notes on the cases under their care and for their observations on the treatment.

HEREDITARY HAEMORRHAGIC TELANGIECTASIS

BY

D. CAPPON, M.R.C.S.

R.M.O., Dorset County Hospital

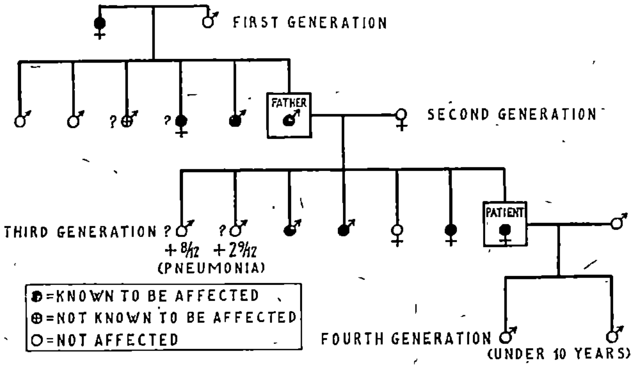
This comparatively rare disease is also known as Rendu-Osler-Weber's disease or Goldstein's heredofamilial angiomatosis. It is defined as a hereditary dystrophy of the capillaries, the disease being transmitted as a Mendelian dominant and affecting both sexes equally. The diagnosis is based on the following criteria: (1) it is hereditary and not sex-bound; (2) the presence of telangiectases or angiomatosis; (3) the tendency to haemorrhage (Goldstein); to which a fourth may be added—the multiplicity of the lesions.

Although W. Legg first described a case in 1876, he presented it as a case of "haemophilia." Rendu in 1896 distinguished it from haemophilia, and Osler in 1901 described all its features. Parkes Weber described a family in 1907 and reviewed the literature in 1924. Goldstein (1932) made an extensive review of the literature, mentioning about 100 families (affecting 600 persons); but Hurst thought this review only caused confusion, since it included every kind of purpura and haemophilia and even a case of familial nephritis. Hurst and Plummer believed this condition to be more common than the number of cases on record would indicate; Price goes further in expressing the belief that it may be as common as haemophilia. The disease should not be diagnosed unless the patient shows multiple telangiectases with haemorrhage and comes from a family one or more members of which are known to have been affected in the past (Hurst and Plummer). Levy in 1933 stated that there were 320 known cases, all familial, though sporadic forms may arise. Hurst and Plummer (1932), Hampson (1932), and Yates (1932) made valuable contributions by reporting complete family histories of this condition. More recently (in 1944), while the case recorded below was being studied with a view to publication, since it shows unusual features, Campbell published a very similar case, and, following this, Wolfsohn added yet a further case to the literature.

Case Record

Mrs. C., aged 31, was admitted to hospital for a dilatation and curettage for incomplete abortion. Apart from this she wanted her blood condition investigated as she felt worried about it. The history was that since the age of 10 she had suffered from epistaxis, which soon became frequent and uncontrollable. She bled more from the right nostril than the left. Bleeding would start spontaneously at any time, day or night. It increased in frequency from once fortnightly to nearly every alternate day. It formerly ceased spontaneously, but now she has to control it by application of cold water and finger pressure. In some severe attacks she "bled white," having lost 1 to 1½ pints (her estimate) in the course of 1½ to 2 hours, which was the longest time bleeding continued. As a result she was always anaemic as a girl, suffering from lassitude and periodic swelling of the ankles, which prevented her from carrying out ordinary household duties. When free from attacks for a more prolonged period—i.e., two or three weeks—a strikingly high colouring of the cheeks had been observed. In such an instance her blood picture was: Hb, 112%; R.B.C.s, 6,250,000; C.I., 0.9; W.B.C.s, 7,000; and on the strength of this and the history of bleeding she was diagnosed as a possible case of "polycythaemia" and told to avoid red meat, and the iron which she was taking regularly was discontinued. She also complained of headaches, which started at the age of 10. Often these headaches, which were parietal and frontal, preceded the epistaxis, and the only thing which seemed to make them better was a "good nose-bleed." She never had vomiting, fortification spectra, or blurring of vision. At about the same age she noticed that some red spots had appeared on her face. The first was on the right upper lip, then next on the tongue and cheeks and in the mouth. Lately she had discovered a few on the ends of her fingers. She has never bled from these spots. In the family history we find that her father had similar spots all over his face and fingers. One such bigger spot used to bleed. He also had severe headaches preceding epistaxis; the latter came from spidery naevi on both sides of the nasal septum. His case was regarded as thrombocytopenic purpura, but no blood reports are available. Transfusion was considered, though his heart condition was thought to make this too hazardous a procedure, so it was not performed. These symptoms increased in severity in middle life, and he died at 66 from severe loss of blood and mitral stenosis.

Further details of the family history are shown in the accompanying chart. Nearly all had epistaxis and telangiectasis, but a history of headaches could not be ascertained.



The obstetric history is that the patient has *two* live children and there have been two miscarriages. Menses are regular; there is no excessive loss. On the contrary, the tendency is to lose less now than formerly. Tonsillectomy was performed at 18, after which she had violent bleeding. There is no history of haemorrhage from anywhere else. A careful examination of the patient was carried out 8 weeks after her dilatation and curettage. Signs of anaemia were present—e.g., pale conjunctivae, lips, and koilonychia. Multiple asymmetrical telangiectases were present, mostly distributed over the upper lip and tip of the tongue, and on the cheeks; they were flat round spots with a red centre and paler periphery. It was remarkable that their colour disappeared, diminished, or remained unchanged on vitropression, according to their size, intensity of colour, and situation. Thus the very dark ones and the larger spots on the cheeks would be unaffected, but the smaller spots on the lips and tongue would disappear. This confirms the finding of Aubertin *et al.* (1933). The blood pressure was 130/70, and Hess's test was negative. Anterior rhinoscopy revealed a spidery naevus 1½ in. by 1/4 in. on the right septum about 2 in. from the external nares. This had a scab on it, and bled with the slightest trauma. Several other spots were present on the left anterior turbinate and in the hypopharynx. The liver and spleen were impalpable. The cardio-respiratory system showed nothing of note. The blood picture (after a haemorrhage) was: Hb, 66% (Sahli); erythrocytes, 4,400,000; C.I., 0.8; leucocytes, 9,500; reticulocytes, 1.5%; Wintrobe V.I., 0.80; differential white count, normal; coagulation time, 2½ minutes; bleeding time and clot retraction, normal; platelets, 400,000. Some weeks later the blood showed: Hb, 55%; R.B.C.s, 4,500,000; C.I., 0.6; platelets, plentiful.

A series of skull radiographs were taken and examined, stereoscopically for a calcified angioma or naevus, but no abnormality was found.

Discussion

In the differential diagnosis haemophilia, pseudo-haemophilia, erythraemia, the purpuras, leukaemia, Banti's syndrome, and hypertension have been excluded. The unusual feature was that in this case epistaxis caused evident clinical anaemia (Lévy), but at times there was polycythaemia. In view of the fact that this occurred when the patient was free from an attack for some 3 weeks or more, it is suggested that it was due to a physiological bone-marrow response to repeated haemorrhages: such over-compensation is known to result from excessively frequent blood donation by healthy persons. No previous reference to polycythaemia in this condition could be found, though Lévy in 1933 stated that the haematological picture may vary. The headaches were another unusual feature. Campbell's case differs in that the headaches have a more pronounced migrainous character, though they do not justify the use of the term "migraine," which is usually applied to a well-defined clinical entity. There are no previous case reports of this condition being associated with headaches, excepting the mention by Osler (1938) of the association of Lindau's syndrome in angiomatosis—a calcified pial angioma accounting for the headaches and other complaints (glaucoma); Hurst in 1932 also mentioned the possibility of angioma of the brain. It is suggested that in both Campbell's case and the present one the headaches may be due to a relative polycythaemia causing engorgement of the cerebral vessels and terminating by epistaxis. In two cases of the second generation of this patient's family epistaxis could not be definitely ascertained; the presence of the malady is, however, not excluded, since they may have been "frustrated forms" (Lévy, 1933). It is interesting to note that this patient did not suffer from menorrhagia—which is in agreement with the literature. A study of the family history favours Campbell's view that the prognosis of the disease is better than that given by Osler, although the condition obviously aggravates concomitant disorders. The immediate treatment of epistaxis is to control it by the inflated-finger-stall method; later, cauterization of the bigger naevi may be carried out—though new naevi are likely to appear.

Summary

A case of hereditary haemorrhagic telangiectasis with a family history of four generations and presenting some unusual features is reported. The literature is discussed in relation to this case.

My warm thanks are due to Mr. G. O. Taylor, Honorary Surgeon, Dorset County Hospital, for allowing me to publish the case; and to Dr. T. V. Cooper, County Pathologist, for the pathological investigations, for indicating the probable diagnosis of the case, and for help and encouragement in preparing this report.

The Ministry of War Transport has notified owners and masters of merchant ships that dimethyl phthalate is now included in the medical scales and should be used as a repellant against mosquitoes when vessels are in malarious areas. The instructions for use are: After sunset a few drops of the liquid should be placed in the hand and applied to the exposed parts of the body, avoiding the eyes, the forehead just above the eyebrows, and areas around the mouth. The liquid should also be applied to the clothing if mosquitoes are biting through it. The effect of the repellant lasts for only about four hours, and a further application should be made when mosquitoes renew their attack. As dimethyl phthalate is a solvent for lacquer, paint, and plastic articles, it should not be smeared on spectacles, watch-glasses, fountain-pens, etc.

NEWER CONCEPTS OF BREAST-FEEDING

BY

M. WITKIN, M.D., F.R.C.P.Ed.

The decline of breast-feeding among civilized races gives the greatest concern to the medical profession. It is the endeavour of the paediatrician to explore every possible avenue in order to remedy this disconcerting state of affairs. With this objective I wish to draw attention to the importance of expressing some breast milk immediately *before* each feed, and the advantage of giving at each nursing *both* breasts instead of one. This routine distinctly helps the proper establishment of lactation.

Most textbooks on paediatrics stress the importance of completely emptying the breast *after* each feed. It is claimed that this is a *sine qua non* for the maintenance and stimulation of an abundant milk supply. It is mainly for this reason that only one breast is permitted at a feed. Although mothers are instructed to empty the breast completely after each nursing, relatively few carry this out—first, because it is very irksome, and, secondly, because the improvement observed is almost negligible. The emptying of the breast at the *end* of each nursing is in my experience not nearly so helpful as the expression of some milk *just before* baby is fed.

The lactating mammary gland consists of 12 to 20 lobes round the nipple. Each lobe is a miniature mammary gland and is composed of smaller lobules. Each lobule consists of a number of alveoli lined with large epithelial cells. The relationship of the lobules and the alveoli to the main duct of the lobe is analogous to that of a bunch of grapes to its stalk. Each alveolus possesses a duct, and the alveolar ducts from each lobule unite to form larger ducts, and finally form the main canal which expands in the areola as the lactiferous sinus. These sinuses, which serve as milk reservoirs, contract at the base of the nipple and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. The surface of the nipple is corrugated and provided with secondary papillae. It is perforated by from 12 to 20 excretory ducts, the orifices of which appear at the bottom of these corrugated papillae.

Failure in a large percentage of breast-feeders can be traced to a block either within the lumen of these fine ducts or at their exits. Such obstruction must lead to an accumulation and damming back of milk in the sinuses, ducts, and the whole parenchyma concerned. The effect of such back pressure is engorgement and a lumpiness in the mammary gland which, unless relieved, may lead to resolution and retrogression of that particular sector of the breast. In this way the baby is deprived of a quantity of milk which would otherwise have been contributed by that portion of the gland. In the course of days other ducts may become similarly occluded, with further loss of nourishment for the baby. Thus the condition becomes distinctly aggravated. The mother finds that she has on her hands a restless and unhappy baby, failing to thrive and plagued with intestinal colic as a result of insufficient food and excessive swallowing of air.

The destiny of the breast parenchyma, when there is duct occlusion within either the areola or the nipple, is as follows: There is a damming back of the milk throughout the lobe concerned, and if several are so involved the breast becomes distinctly heavy and painful. Instead of the tissues being lax and freely mobile so as to enable the infant to pull the areola well into its mouth, they become tense, hot, and unyielding, and the baby finds great difficulty in grasping the breast. Its efforts are mostly spent on the base of the nipple rather than well over the areola, with the result that the papilla often cracks. This not infrequently leads to an ascending infection and sometimes to a breast abscess.

Importance of Expressing Some Milk before Feeding

The question which immediately presents itself is, What factors are responsible for occlusion of the lactiferous ducts? It is quite obvious that such minute canals could easily become blocked either by milk products within the areolar sinuses or nipple ducts; or through the viscosity of colostrum in the early days affording resistance to outflow. The openings of the ducts on the surface of the mammary papilla are often occluded by coagulated milk, toilet powder, or desquamated epithelium due to the friction of clothing on the nipple itself.

If we examine the manner in which milk leaves the breast of a mother whose baby is adequately and successfully fed we find, on manual expression, the number of jets expelled from the nipple are many—12 or more. They do not appear all at once—usually three or four at a time—depending on the site of pressure exerted on the areola by the thumb and forefinger of the expressing hand. This demonstrates that the successful functioning of the breast depends mainly on the patency of the ducts. In cases where difficulty prevails we find only one or two jets appearing, and no more. This obviously is accounted for by the occlusion of the remaining ducts either within the areola or nipple or at their exits. The food thus meets with resistance in leaving the breast. It is obvious, therefore, that the baby of such a mother cannot possibly be satisfied or thrive. Should this be discovered in the early days of the infant's life one is able, in a large percentage of cases, to correct the abnormality by teaching the mother to express some milk from each breast (about one or two teaspoonfuls before each feed) and advising feeding from *both* mammae at every nursing.

The technique of manual expression is simple. The mother should wash her hands thoroughly and dry them with a clean towel. The nipple and areola should be cleaned with pledgets of cotton-wool dipped in boiled water, and dried. A clean glass or other receptacle will be necessary to receive the fluid. It is more convenient to employ the hand opposite the mammary gland concerned. The mother should grasp the breast between the thumb above and the forefinger below, just outside the margin of the areola, which is pressed and squeezed with a firm but gentle follow-up action converging on the base of the nipple; this pressure, terminating with a slight pull behind the base of the papilla, coaxes out the milk. About 30 to 60 expressions are made per minute. Both breasts are treated in similar fashion *before* each feed; this should not take more than five minutes. Should the mother regard the expressed milk as a waste she can offer this to her baby by spoon or dropper, suitably warmed, after the breast feed. Immediately after the ducts have been cleared by this preliminary expression the baby is given one breast for 5 minutes and then the other for 15 minutes. As a result of this manœuvre the milk will be found to flow more freely and abundantly. The child will thus obtain a larger quantity of nourishment, be more contented, and thrive.

Mothers are emphatic that this method of preliminary expression is far more beneficial and easier of execution than the common teaching of completely emptying the breast *after* each feed. Provided the ducts are patent and their openings function properly there will be no engorgement. Once the outflow of milk becomes free and conditioned the breasts take care of themselves and become adapted to the demands of the child.

Importance of Giving Both Breasts at Each Feed

In my experience the use of *both* breasts at each suckling is a distinct advantage over the orthodox teaching. The mother is instructed to nurse her baby 5 minutes on one breast and 15 minutes on the other. Provided the ducts and sinuses have been cleared by preliminary expression in the manner described there is no fear whatever of the breasts retrogressing as a result of not being "completely emptied" after each performance. We are apt to forget that when a baby feeds on one breast the other gland is reflexly stimulated. This would serve no useful purpose unless it was Nature's intention that both breasts should be suckled from.

When only one breast is employed at a feed the gland is relieved once in 8 hours in the four-hourly feeding schedule and once in 6 hours if three-hourly feeds are given. This definitely is not sufficient stimulation. In bilateral feedings both breasts are relieved every 3 or 4 hours, and this method is far superior in establishing milk flow. As the lactating breast is constantly secreting milk, complete emptying is almost impossible. The teaching that any milk left in the breast after feeding eventually seals its doom is in my experience a myth.

Who would venture to assert that the successfully breast-fed baby completely empties the mammae at each feed? I feel convinced that Nature no more expects it to inhale and exhale *completely* with each inhalation and exhalation or the lacrimal glands to drain *completely* with each bout of weeping in order to sustain its subtlety. Once outflow is free and fully established, resolution seldom occurs so long as the mother and child are well.

It must be impressed on the mother that all healthy babies consume half their feeds within the first two minutes; that within five minutes they have swallowed two-thirds or three-quarters of the total feed, and that very little milk, if any, is consumed after 20 minutes of suckling. It is for this reason that I recommend only 5 minutes on the first breast and 15 minutes on the second, or sometimes 5 minutes on the first breast, 10 minutes on the second, and again 5 minutes on the first.

The importance of not allowing the child to spend more than 20 minutes at each feed cannot be exaggerated, as infants who are fed for periods of 30 to 45 minutes or longer almost invariably give trouble. After 15 or 20 minutes the child swallows large quantities of air, which cause colic, restlessness, crying, and sleeplessness. Furthermore, the gums and tongue become painful. If the mouth of such an infant is carefully examined the teething edges of the gums and the tip of the tongue are often found to be raw, inflamed, and angry-looking. This explains why such a child often refuses the breast. The mother in turn suffers as a result of the considerable trauma on the nipple through prolonged suckling.

There are other desiderata of vital importance. The mother, needless to say, must be willing and keen to feed her baby. She must be prepared to devote most of her time to the new arrival, especially during the first two months. She should make all necessary arrangements at least 15 minutes before each feed—about 5 minutes of which should be devoted to the toilet of the nipples and their preliminary expression. She should be seated comfortably in a low chair and so placed that the nipple falls easily into the baby's mouth, and should ascertain that the infant can breathe freely through its nostrils. While she is feeding her infant she should be alone in her room and not disturbed, in order to give her undivided attention to her babe.

Summary

- Every mother should express some milk from *both breasts* just before each feed. This is more helpful than emptying the breast *after* the feed. This procedure ensures the patency of the lactiferous ducts and free outflow of milk. The use of both breasts at each feed, 5 minutes on the first and 15 minutes on the second, is strongly recommended. The above procedures obviate feeding troubles in many cases.

UNILATERAL HYPOTONY DURING ANAESTHESIA

BY

INA BRITTAIN, M.B., B.Ch., B.A.O.

AND

G. J. C. BRITTAIN, M.D.

Apart from the findings of Lyle and Fenton (1934) there appear to be no references in the current literature with regard to a decrease in the intraocular tension during anaesthesia, and none in which a unilateral reduction in intraocular tension is described from any cause during general anaesthesia.

It is the object of this contribution to show that during anaesthesia a unilateral reduction in intraocular tension may take place from pressure exerted on the globe by a badly adjusted rubber face-mask. The condition was first discovered after an anaesthesia of 1½ hours' duration, under which an extensive repair was necessary for a badly crushed and lacerated hand. Pre-operative medication consisted of morphine 1/6 gr. and hyoscine 1/150 gr.

The patient, a man aged 45, was induced with pentothal sodium followed by nitrous oxide and oxygen, using a closed-circuit technique. Small amounts of pentothal sodium were added from time to time during the course of the operation, 15 c.cm. (0.75 g.) in all being used. On removal of the face-mask at the end of the operation it was at once noticed that the inflated rubber rim of the mask had been resting directly over the right globe and there was a small reddened area extending from the inner third of the supraorbital margin to the centre of the infraorbital margin in a direct line across the lids. The right pupil was found to be widely dilated and the left contracted. (Anaesthesia was at this time light, the patient being only in the upper plane of the third stage.) A very sluggish light reflex was obtained on the right side, and the intraocular tension was found on palpation to be so much reduced that it was thought a posterior rupture of the globe might have been overlooked before the start of the operation. An examination of the fundus was attempted, but owing to the dryness of the cornea no detail could be defined. A more accurate estimation of the tension was obtained by the use of the Schiötz tonometer, showing the tension in this eye to be below 10 mm. Hg. The tension of the other eye was within normal limits. (See Case 1, Table I.) On examining the patient the day after operation it was found that the tension in the right eye had improved. No history of any previous eye symptoms could be obtained from the patient and there was no history of injury. The tension continued to improve and the patient was seen by the honorary ophthalmic surgeon, who confirmed the decrease in tension and absence of any other pathological condition. On the tenth day after operation the tension was equal to that in the other eye and the visual acuity was normal in both eyes.

As this case was of considerable interest from both the ophthalmological and the anaesthetic points of view, it was decided in future to examine cases as a routine immediately after operation—both where the anaesthetic mask had been fitting closely over one eye and otherwise—in order to determine whether any changes in the intraocular tension had taken place; also to try to discover whether the condition was produced purely by pressure from a closely fitting mask, or if the type of anaesthetic used, the condition and age of the patient, or length of operation helped to play any part. A unilateral reduction in intraocular tension was demonstrated in 13 cases (Table I) by such an investigation, carried out after routine operations on 300 cases at the Derbyshire Royal Infirmary.

It can be seen from this table that cases occurred after all types of operation, irrespective of age, nature or length of operation, or type of anaesthetic in use. The only constant feature in each case was the fact that the mask had been fitting moderately tightly over one eye, although in no instance had any extreme pressure been applied. The degree of "tightness" of the mask was just sufficient to ensure that no leakage occurred with the closed circuit in use. Although pentothal sodium was employed for induction and/or maintenance of anaesthesia in six of these cases, with the exception of three cases (Nos. 1, 12, and 13) the lowering of intraocular tension was no greater than with any of the other anaesthetic agents in use. It should, however, be noted that it was in these three particular cases out of the whole series that the greatest decrease in intraocular tension occurred. The type of mask used in all cases was either the McKesson or the ordinary face-mask with an inflatable rubber rim, held in place by Clausen's harness.

TABLE I

Case No.	Age	Operation	Length of Operation	Anaesthetic	Tonometer Readings	
					Immediate	When Normal
1	45	Lacerated hand	1½ hours	Pentothal, N_2O & O_2	R. below 10 mm. Hg L. 25 mm. Hg	On 10th day
2	22	Compound fracture and laceration of leg	1 hour	N_2O & O_2, ether	R. 14 mm. Hg L. 25 mm. Hg	6 hours later
3	76	Strangulated inguinal hernia	¾ ,,	N_2O & O_2, cyclopropane	R. 18 mm. Hg L. 25 mm. Hg	10 ,, ,,
4	50	Suprapubic cystotomy and ligature of vas	20 mins.	N_2O & O_2	R. 20 mm. Hg L. 10 mm. Hg	10 ,, ,,
5	35	Perforated gastric ulcer	40 ,,	N_2O & O_2, ether	R. 16 mm. Hg L. 25 mm. Hg	48 ,,
6	47	Radical mastectomy	1 hour	Pentothal, N_2O & O_2, ether	R. 15 mm. Hg L. 28 mm. Hg	9 ,, ,,
7	72	Strangulated inguinal hernia	¾ ,,	N_2O & O_2, ether	R. 12 mm. Hg L. 28 mm. Hg	4 ,, ,,
8	54	Compound fracture-dislocation of ankle	¾ ,,	Pentothal, N_2O & O	R. 25 mm. Hg L. 15 mm. Hg	8 ,, ,,
9	22	Appendicectomy	1 ,,	N_2O & O_2, vinesthene	R. 14 mm. Hg L. 27 mm. Hg	5 ,, ,,
10	56	Excision of vulva	1¼ hours	N_2O & O_2, trilene	R. 12 mm. Hg L. 30 mm. Hg	5½ ,, ,,
11	42	Intestinal obstruction	1½ ,,	Pentothal, cyclopropane, oxygen	R. 28 mm. Hg L. 15 mm. Hg	7 ,, ,,
12	52	Crushed hand	1 hour	Pentothal, N_2O & O_2	R. 10 mm. Hg L. 28 mm. Hg	9 ,, ,,
13	58	Intestinal obstruction	1¼ hours	Pentothal, cyclopropane, oxygen	R. 30 mm. Hg L. below 10 mm. Hg	11 ,, ,,

Following on the above observations, it was decided to try to produce the phenomenon artificially in the unanaesthetized patient, and we are indebted to several colleagues who volunteered for the experiment. An ordinary mask was strapped over the face in such a way that the inflatable rim covered one eye, using only moderate pressure. After 30 to 40 minutes the mask had to be removed owing to severe pain experienced in this eye, and it was then noticed in all cases that the tension of the eye in question was decreased. This was confirmed by tonometer readings (see Table II). Some blurring of vision and pain in the affected eye were noticed for two to three hours, and the intraocular tension had returned to normal within six hours or less in all cases. Examination of the fundi revealed no abnormality.

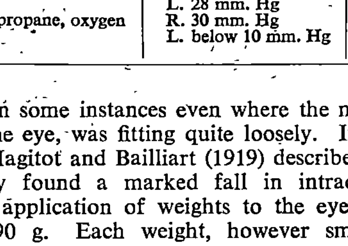
TABLE II

Case	Length of Time Mask kept on Face	Tonometer Readings	When Normal
A	½ hour	R. 28 mm. Hg *L. 13 mm. Hg	2 hours later
B	½ ,,	*R. 14 mm. Hg L. 25 mm. Hg	5 ,, ,,
C	40 mins.	R. 24 mm. Hg *L. 10 mm. Hg	4 ,, ,,
D	35 ,,	*R. 15 mm. Hg L. 20 mm. Hg	5
E	½ hour	*R. 15 mm. Hg L. 28 mm. Hg	2½ ,, ,,

* Denotes eye on which pressure was exerted.

The findings obtained seem to indicate that the reduced tension is entirely due to the pressure exerted by the face-mask, and when this fall in tension occurs during anasthesia no other factor plays any great part in its production. As the configuration of the face varies considerably with the individual it is not always easy to adjust the mask to conform accurately to the contour of a particular face and thus maintain the air-tight connexion so necessary for use with a closed-circuit technique. Careful choice of the individual size and shape of the mask must be made, otherwise the rim will in many cases unavoidably rest wholly or in part on the globe of one eye, producing an abnormal pressure on this eye and a fall in the intraocular tension.

The degree of pressure exerted by the face-mask in these cases was not severe, and changes in the intraocular tension were noticed in some instances even where the mask, although pressing on one eye, was fitting quite loosely. It is interesting to note that Magitot and Bailliart (1919) described experiments in which they found a marked fall in intraocular tension following the application of weights to the eye which varied from 10 to 90 g. Each weight, however small, caused a diminuition in tension in normal eyes. Pressure exerted by an anaesthetic mask is of course far in excess of 90 g. On the application of artificial pressure to the globe there is a transient rise in intraocular pressure which leads to the expulsion of the intraocular fluid through the canal of Schlemm and a consequent fall in the tension, which is in turn followed by a prolonged rise due to the effects of the vascular reaction involved (Duke-Elder, 1940). The gradual rise to normal tension in the affected eye noted in this series of cases has taken on an average 6 to 9 hours, although Case 1 took as long as 10 days. This gradual return to the normal intraocular tension is immediately followed in all cases by a rise in tension above the normal (as compared with the other eye), which may be maintained for several hours—nine hours being the longest recorded here, while on the average it has been two to four hours (see Graph). This is followed by a return to the normal tension, at which it remains constant.



Graph showing time taken in an average case for the tension to return to normal, followed by a rise above normal lasting between 2 and 4 hours.

This rise above the normal tension, which is occasionally pronounced and may be prolonged, is of importance, as it seems likely that an acute glaucomatous attack may in this way be precipitated in a susceptible patient. It may be that the development of an acute glaucoma, which on rare occasions follows operation and which has previously been ascribed to premedication with atropine, may really have been due in whole or part to this phenomenon. It is necessary to point out that in this series of cases hyoscine and not atropine was used pre-operatively; all readings were taken with the Schiötz tonometer, and in conscious patients gutt. holocaine 1% was used as a local analgesic.

Summary

Thirteen cases of unilateral hypotony have been described following anaesthesia in a series of 300 cases.

The aetiological factor has been shown to be the pressure exerted by the rim of a badly adjusted face-mask, and the importance of the choice of a correct size and shape of mask is stressed.

The nature, length of operation, age and condition of the patient, and type of anaesthetic used, seem to play little or no part in the production of this unilateral hypotony, although pentothal sodium, which is known to cause a bilateral reduction in tension, no doubt tends to exaggerate the effects caused by pressure, as instanced by Cases 1, 12, and 13.

The possibility of the occurrence of acute glaucoma in the affected eye should be borne in mind, as the lowered intraocular tension is followed by a rise above the normal which may last for some hours.

We are indebted to Mr. C. H. Bamford for his continued help and encouragement during this investigation, and also to the other members of the honorary surgical staff for permission to publish their cases.

PSYCHOLOGICAL REACTIONS IN THE WOUNDED

BY

LOUIS MINSKI, M.D., F.R.C.P.
Medical Superintendent, Sutton Emergency Hospital

Apparently it is a fairly commonly held view that the wounded who develop neuroses have only slight injuries and that those who are severely wounded rarely suffer from neurosis. The reason given is that those who have severe wounds are sure of being removed from the fighting area, at least for some considerable time, while the man with a slight wound may return to the front line in the course of a few days. According to those who hold this view, the neurosis is therefore an escape mechanism.

Investigation of a Group admitted with Neuroses

The development of a neurosis cannot be explained in this simple manner, and in order to ascertain the true facts of the relation of wounds and neurosis, 54 patients who had been wounded and were admitted to the neurosis centre here were investigated. Of these, 39 were suffering from anxiety states, 8 from depression, and 7 from hysterical states. Their wounds were divided into three categories—viz., severe, moderate, and slight. In the first category were included, for example, mortar wounds of the right side of the face and the right leg (compound fracture), penetrating wounds of the chest, petrol burns of the face, neck, arm, etc. Among the moderate wounds were included g.s.w. of the right calf, g.s.w. of the left shoulder and forearm, shrapnel wounds of the mouth, etc.; while the slight wounds consisted of bullet wounds of the fingers, superficial shrapnel wounds of the arm, etc. No head wounds were included, because of the special circumstances and symptoms associated with the post-concussive and post-traumatic syndromes.

On this basis 24 patients had sustained severe, 26 moderate, and only 4 slight wounds. In assessing the category into which the patient should go, the wounds were regarded as being less severe than they actually were, so that over-emphasis was not laid on the severity of the injury. It will be seen, therefore, from these figures, that those with slight wounds are not the ones who predominantly develop neuroses. In investigating these cases, however, several interesting points emerged.

First, constitutional predisposition is the most important factor, and was present in 46 of the 54 cases. This consisted of a neurotic, psychopathic, or psychotic family history, a neurotic personality (timid, worrying, moody, seclusive, inadequate, etc.), or a poor work record. In 23 cases there was a combination of a positive family history and a neurotic personality. This constitutional element is by far the most important factor in determining a neurosis, but by no means the only one.

Another striking feature is that of these 54 patients 46 had what may be called extremes of length of service. In other words, the men who had short service—viz., from 1 to 1½ years—and then went into action, or those with 4 years or more, and were wounded, seemed to be more prone to break down. This may be due in the former to a lack of confidence and the fact that they had not been in action before. By this it is not suggested that all men who go into action for the first time and are wounded develop neuroses; but these men had, as stated, a constitutional predisposition. When men have been in action together for some time a marked feeling of camaraderie develops which helps to give the neurotic a feeling of confidence.

Many of the men with long service had been through severe stresses already—viz., the evacuation from Dunkirk, fighting in N. Africa, Italy, Tunisia, Burma, etc.—and the cumulative stresses, together with four to five years' separation from their families, were sufficient to produce neuroses in constitutionally predisposed persons. Many of these patients, although somewhat anxious and apprehensive in action, were able to carry on until they saw their pals being killed at the same time that they themselves were wounded, and this often precipitated a neurosis.

A personal worry is often the final precipitating factor. For example, one patient who was wounded by a flying bomb in Belgium was perfectly all right until he realized that his family was in a part of this country exposed to flying-bomb attacks. He then became anxious and apprehensive. Another patient, who was at Arnhem, had mild anxiety symptoms, which became acute on arriving in this country when he found out that his wife, who was pregnant, had been bombed out and had no home to which to take the baby when it arrived. Much can be done by the welfare authorities to help patients in clearing up their domestic worries.

Another factor in some cases was the extent to which the wound would interfere with the patient's peacetime career. Here reassurance or the use of the Ministry of Labour scheme for retraining of disabled men can help in overcoming this difficulty. The proportion of volunteers to conscripts was 22 to 32, and did not seem to be of any great significance. Nor did the question of age, which ranged from 19 to 38.

Analysis of a Group admitted for Surgical Treatment only

At the same time that those wounded who were admitted with diagnosed neuroses were examined, 38 wounded patients on the general side of the hospital were examined from the psychiatric point of view. Of these 38 cases, 18 were regarded as seriously wounded, 17 moderately, and 3 slightly. Although these patients were admitted for treatment of their surgical conditions only, 17 were suffering from definite anxiety states. All the 17 showed marked constitutional predisposition, and of the wounds 10 were regarded as moderate and 7 as severe.

In addition to these 17 patients, who required active psychiatric treatment, 11 others had anxiety symptoms for several weeks after they were wounded. These symptoms consisted of anxiety dreams in which they relived their battle experiences, palpitation, sweating, and a feeling of tenseness. Many of these men were considerably upset by air-raid alerts and sudden noises, whereas they previously had been quite unperturbed by them. When tied to their beds by extensions, etc., several complained of a feeling of helplessness when the alert went, and said they felt their "stomachs" turn over, they sweated, and their hearts thumped. Most of these patients were considerably helped by being given sodium amytal 3–6 gr. at night, and none of them showed any marked constitutional features.

Two of these cases of frank neurosis were first diagnosed by the sister of the surgical ward, as on coming round from the anaesthetic after their operation the patients began to abreact their battle experiences. The psychiatrist on duty was called by her, and he continued the abreaction; and a day or two later these patients stated that they felt much less tense and anxious than before the operation. The remaining 10 patients showed no neurotic symptoms and had very stable personalities.

The age distribution and length of service were similar to those for the group admitted with neuroses, while the proportion of conscripts to volunteers was also comparable.

The degree of severity of a wound bears little or no relation to the development of a neurosis. Constitutional predisposition in the form of a positive family history, neurotic personality, or poor work record is the most important factor, while personal and domestic worry, severe battle stress, and length of service appear to be contributory factors.

It seems certain that a large proportion of wounded (in this series 28 out of 38=73%) suffer from undiagnosed anxiety or other neurotic symptoms, and it would seem important to question each battle casualty in base hospitals as to whether he suffers from battle dreams or other anxiety symptoms. In many cases the mild symptoms will clear up on giving sodium amytal, while the more severe cases should be referred to a psychiatrist.

Medical Memoranda

Uraemia and Heat-stroke: An Exercise in Diagnosis

The following case illustrates the importance of thinking again when signs and symptoms point to a certain diagnosis but the general clinical picture is not typical of, or even consistent with, the disease diagnosed. As my primary object in publishing it is to illustrate a diagnostic argument, I will describe the case as the problem presented itself and not as a clinical case sheet.

Case History

A lad aged 20 complained of pain in the right groin, and frequent micturition with pain in the penis, after a route march in Italy. His M.O. found a tender swelling in the groin which was "reduced easily into the scrotum" and must have been the right testicle. He was admitted to the V.D. wing, where he continued to complain of dysuria and started vomiting. He had had two days' constipation. There was a rash on his body which was thought to be a sweat rash. He was transferred to the surgical division because strangulated hernia was suspected and there was no sign of venereal disease.

The surgeons found that there was a heavy albuminuria; the urine, in fact, solidified on boiling. There were also granular casts. He was somewhat vague mentally and lethargic; his tongue was dirty, and his temperature 101° F. He complained of weakness in the legs. The blood urea was estimated and found to be 108 mg. per 100 c.cm. The triumphant diagnosis of nephritis with uraemia was made, and the case was shown to the physicians as a *fait accompli.*

The physicians, however, had the bad taste to remark that the case conformed with no known type of nephritis. This was looked upon as a confession of ignorance, but it was argued that nephritis did not account for the frequent desire to pass small quantities of urine or for the pain on micturition. It could not be a case of terminal renal failure as the urine was highly coloured and well concentrated. If, on the other hand, it was acute nephritis severe enough to cause uraemia, why was there no haematuria, oedema, or hypertension? (The blood pressure was 105/90.)

A period of contemplation on renal and extrarenal causes of uraemia ended with the sudden revelation that it might be a case of heat-stroke. The patient was questioned again, and stated that the route march took place at the end of a "scheme" which had entailed several days' marching in the heat of the sun. On the final day he had been taking turns in carrying a heavy weapon in addition to his own equipment. Memory was refreshed by reference books, and it was established that the following symptoms may occur in heat-stroke: Mental changes, especially abnormal behaviour, leading in some cases to charges of insubordination; weakness and cramps; frequent micturition with pain in the penis; albuminuria; high blood urea; vomiting; loss of knee-jerks. The knee-jerks were tested and found to be absent. A qualitative test showed that chloride was virtually absent from the urine.

The forecast was made that with rest, fluids, and salt the patient would be cured in a few days. This was received with much scepticism, for in the minds of the surgeons albuminuria and uraemia could only mean Bright's disease. On the following day the blood urea was 88 mg., the mental condition had improved, the albumin was much less, and there were very few casts. Next day the albumin was less than 0.5 g. per litre. Two days later he was much brighter: no albumin, blood urea 48 mg. Five days later he was mentally normal and getting up: no albumin, blood urea 20 mg. per 100 c.cm., urinary chloride still somewhat diminished.

The mental state described in heat-stroke was nicely illustrated in this case. On the first day the patient described his urinary symptoms and the site of his pain in adequate but very vulgar terms, embarrassing in the presence of the ward sister. This was not considered to be diagnostic, as he came from the East End of Sheffield, but two days later gentility had returned and his nomenclature was completely revised.

Robert Platt, M.D., F.R.C.P.,
Physician, Royal Infirmary, Sheffield;
A/Col., Consulting Physician, Southern Army, India.

A Simple Test for the Detection of Bile Pigments in Urine

It has been shown that "adsorption colorimetry" may provide a convenient method for the estimation of coloured substances such as mepacrine (Yudkin, 1945a, 1945b). The principle of this technique is the adsorption of the coloured substance on to a measured amount of white adsorbent powder, the intensity of the colour produced being proportional to the amount of the substance. "Adsorption colorimetry" may also be used for a qualitative test, and the present communication describes a simple method for the detection of bile pigments in urine by this technique. It requires only one reagent.

The Test

Materials.—Test-tubes; silica gel powder (preferably sifted so as to pass 60 mesh but not 120 or 130); a scoop delivering 0.25 ml.
